Reverse Shoulder Arthroplasty Prosthesis Design Classification System

Howard D. Routman, D.O., Pierre-Henri Flurin, M.D., Thomas W. Wright, M.D., Joseph D. Zuckerman, M.D., Matthew A. Hamilton, Ph.D., and Christopher P. Roche, M.S., M.B.A.

Abstract

Multiple different reverse total shoulder arthroplasty (rTSA) prosthesis designs are available in the global marketplace for surgeons to perform this growing procedure. Subtle differences in rTSA prosthesis design parameters have been shown to have significant biomechanical impact and clinical consequences. We propose an rTSA prosthesis design classification system to objectively identify and categorize different designs based upon their specific glenoid and humeral prosthetic characteristics for the purpose of standardizing nomenclature that will help the orthopaedic surgeon determine which combination of design configurations best suit a given clinical scenario. The impact of each prosthesis classification type on shoulder muscle length and deltoid wrapping are also described to illustrate how each prosthesis classification type impacts these biomechanical parameters.

Clinical use of reverse total shoulder arthroplasty (rTSA) has increased dramatically in the USA since its FDA clearance in November 2003. Reported mid-term clinical outcomes continue to support the use of this unique prosthesis; consequently, indications have expanded beyond the diagnosis of rotator cuff tear arthropathy to more complex and challenging disease states and revision cases.[1-9] The most recent ICD-9/discharge data from the National Inpatient Sample (NIS), Healthcare Cost and Utilization Project (HCUP), and Agency for Healthcare Research and Quality databases show that 30,850 rTSA procedures were performed in the US in 2013, which is approaching the 34,155 procedures reported for anatomic total shoulders (aTSA) and nearly three times the 11,180 procedures reported for hemiarthroplasty. Based upon this data, rTSA usage increased 26.1% from 2012 in which 24,465 procedures were performed and increased 40.8% from 2011 in which 21,916 procedures were performed. Similarly, aTSA usage increased 10.5% from 2012 in which 30,920 procedures were performed and increased 16.1% from 2011 in which 29,414 produces were performed. Finally, hemiathroplasty usage decreased 13.5% from 2012 in which 12,920 procedures were performed and decreased 29.5% from 2011 in which 15,860 procedures were performed. Comparing usage with these ICD-9 codes discharge data for total (81.8) and partial (81.81) shoulder arthroplasty with those for rTSA (81.88, which was first reported in Q4 2010), there is a fairly dramatic change in the pattern of utilization over the past decade and a continual shift away from hemiarthroplasty to rTSA (Fig. 1). This shift in utilization is apparent to varying degrees in each of the participating states that contribute to this database. For example, greater than 50% of the shoulder arthroplasty performed in Florida, Arkansas, Kentucky, and North Dakota are rTSA, whereas less than 25% of the shoulder arthroplasty performed in Hawaii, Vermont, and Washington are rTSA (Table 1). Using the most recently available 2013 state data also demonstrates varying degrees of growth in each shoulder prosthesis type. Between 2012 and 2013 in these participating states, there was a 9.7% increase in aTSA, a 14.6% decrease in hemiarthroplasty, and a 27.1% increase in rTSA; and specifically for rTSA, Oregon, Kentucky, and West Virginia all had greater than

40% increase in rTSA usage, while Hawaii, Nevada, and Nebraska all had less than 10% increase in rTSA usage (Table 1).

Furthermore, as clinical experience has increased with usage in different and growing indications, rTSA prosthetic design features have evolved to better address different pathoanatomy. Subtle rTSA prosthesis design parameter differences have been demonstrated to significantly impact the amount of bone removed during implantation,[10,11] glenoid fixation,[12-15] and joint kinematics, including muscle moment arms,[16-26] residual muscle length,[25-30] and deltoid wrapping.[25-27] Such biomechanical changes have clinical implications which can increase or decrease the risk of certain complications as well as the incidence of scapular notching.[31-40] Given the growing number of rTSA prostheses available in the global marketplace, each with its

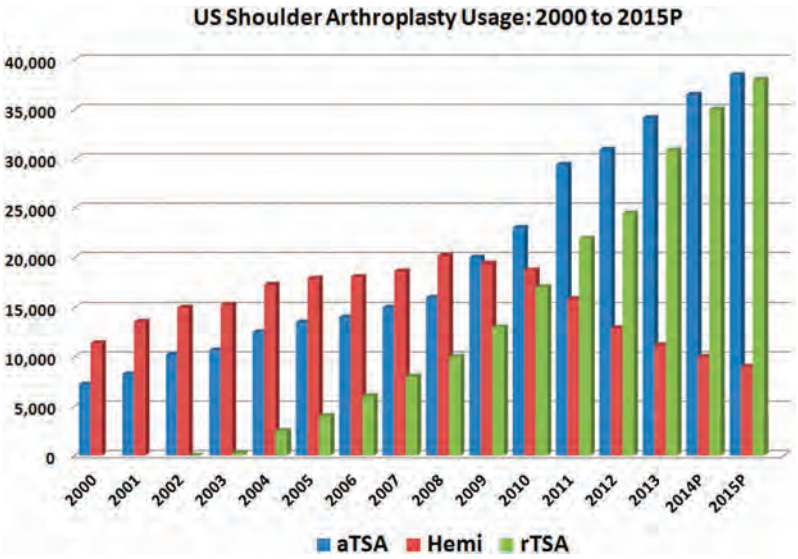

Figure 1 Estimated procedural distribution and usage of shoulder arthroplasty in the USA (2003 to 2015).

unique configuration of design parameters, it is critically important for the orthopaedic surgeon to have a working knowledge of how different combinations of design parameters influence these biomechanical changes. To this end, we propose an rTSA prosthesis design classification system[25,26] to objectively identify and categorize different designs based upon their specific glenoid and humeral prosthesis characteristics for the purpose of standardizing nomenclature that will help the orthopaedic surgeon determine which combination of design configurations best suit a given clinical scenario.

Glenoid Prosthesis Characteristics

For the glenoid prosthesis classification, a glenosphere with a center of rotation (CoR) of 5 mm or less lateral to the glenoid face is considered a medialized glenoid (MG), and a glenosphere with a CoR greater than 5 mm lateral to the glenoid face is considered a lateralized glenoid (LG) (Fig. 2). For a typical glenosphere and baseplate configuration, the position of the CoR is determined by the spherical radius and thickness of the glenosphere, where the difference between the glenosphere thickness and glenosphere radius determines the magnitude of CoR lateralization from the glenoid.

Medialized glenoid designs are associated with a greater medial shift in the CoR relative to the native anatomic joint, which increases the deltoid abductor moment arms, requiring less muscle force to elevate the arm.[16-18,20,22,24-26] However, MG designs shorten the residual rotator cuff muscles, which may negatively impact improvements in postoperative internal and external rotation if not addressed on the humeral side.[21,22,25-27,29] Additionally, MG designs are associated with less deltoid wrapping, which reduces the horizontal stabilizing compressive force vector of the deltoid and may increase the risk of dislocation if not addressed on the humeral side.[25-27] MG designs have also been demonstrated to have an increased risk of scapular notching.[1,3,4,6,31-40] MG designs do, however, experience less shear force at the glenoid-baseplate interface, improving initial glenoid fixation.[13,14] In the clinical setting of an uncorrected

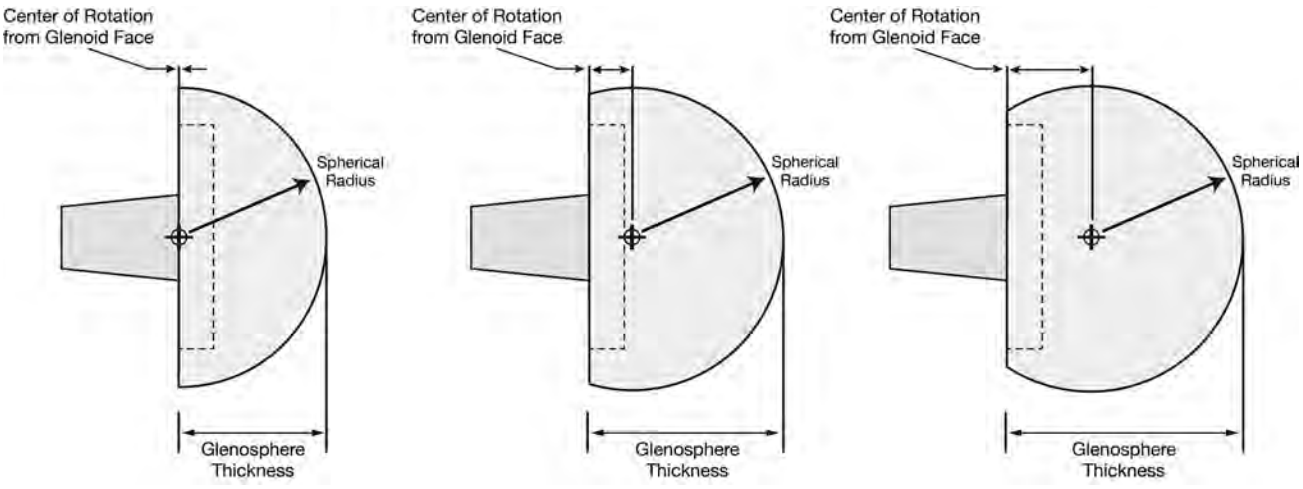

Figure 2 rTSA glenoid prosthesis design classification, representative images of three glenosphere designs having equivalent articular curvatures demonstrating that glenosphere thickness is directly related to the lateralization of the CoR relative to the glenoid face.

glenoid deformity as a result of preoperative glenoid bone erosion, all of the downsides of MG devices can be further exaggerated with instability and loss of external rotation as a result.[25-27,41,42]

Lateralized glenoid designs also medialize the CoR relative to the native anatomic joint, but because the thickness of the glenosphere is at least 5 mm more than its spherical radius, the CoR is laterally shifted from the glenoid face by an amount equivalent to the difference between its thickness and radius. This lateral shift decreases the deltoid abductor moment arms relative to the MG designs but still increases the deltoid abductor moment arms relative to the anatomic joint.[20,22-26] For this reason, LG designs are associated with less efficient deltoids than MG designs; therefore, the deltoid force required to elevate the arm is greater for LG designs, which theoretically can have negative implications on the maximum range of motion achieved postoperatively, the ability to achieve stable glenoid fixation, and also the rate of acromial stress fractures (due to the increased shear force generated by the deltoid).[20,22-26,43] However, LG designs better tension the residual rotator cuff muscles, which potentially improves postoperative internal and external rotation relative to MG designs if not addressed on the humeral side.[25-27,29]

Lateralized glenoid designs also improve the amount of deltoid wrapping relative to MG designs, which increases the horizontal stabilizing compressive force vector of the deltoid and may decrease the risk of dislocation.[25-27] LG designs, being thicker (either by more metal or the use of bone graft), are also associated with less humeral and scapular impingement and therefore are associated with lower scapular notching rates than MG designs.[2,25,26,32-34,41,44] Because of this increased thickness, LG designs may also be a better solution for medially eroded glenoids as they move the joint line more laterally to better restore its native position, potentially improving joint stability and postoperative internal and external rotation.[25-27,41,42,44]

Humeral Prosthesis Characteristics

For the humeral prosthesis classification, humeral offset is defined as the horizontal distance between the intramedullary canal and humeral stem axis to the center of the humeral liner (Fig. 3). A humeral component with an offset of 15 mm or less is considered a medialized humerus (MH), and a humeral component with an offset greater than 15 mm is considered a lateralized humerus (LH). For a typical humeral stem and humeral liner configuration, the offset determines the amount of humeral lateralization and is influenced by humeral neck angle, humeral osteotomy, and use of an inset or onset humeral tray and stem design where an onset humeral design includes a modular humeral tray that sits on top of the resection and may or may not be offset.

Medialized humeral designs are traditionally inset to place the humeral liner within the proximal humeral metaphyseal bone at a non-anatomic 155° osteotomy. Doing so, distally shifts the humerus relative to the native anatomic joint to increase deltoid tensioning.[22,25-28,30,45] MH designs are associated with a larger medial shift in the position of the humerus/greater tuberosity relative to the native anatomic joint and a decrease in deltoid wrapping, which in turn results in less improvement in the deltoid abductor moment arms.[25-27] Furthermore, medializing the humerus also moves the rotator cuff insertions, which shortens the residual rotator cuff muscle length and can have negative implications on postoperative internal and external rotation.[22,25-27,29,45]

Lateralized humeral designs are typically onset to place the humeral tray and liner on-top of an anatomic neck osteotomy, which distally shifts the humerus to increase deltoid tensioning.[22,25-27,29,45] However, by building on-top of an anatomic neck osteotomy, the humerus is pushed more lateral relative to MG designs (though still medial relative to the native anatomic joint).[22,25-27] This results in better re-

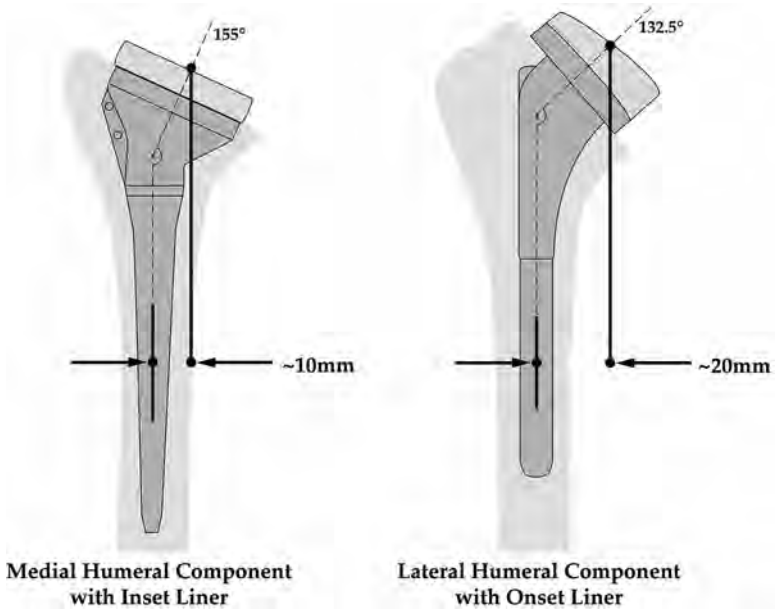

Figure 3 rTSA humeral prosthesis design classification, examples of a medial humeral component with an inset humeral liner (left) and a lateral humeral component with an onset humeral liner (right).

sidual rotator cuff tensioning and better deltoid wrapping to improve stability, which also lengthens the deltoid moment arm to improve joint efficiency.[22,25-27] If a LH design is onset, it may also function as a platform humeral stem, which has numerous clinical advantages and inherent efficiencies.[25-26,46]

Combined Glenoid and Humeral Impact

While the design characteristics of the glenoid and humeral prostheses individually are important to understand, the impact of mating together these devices is the most critical aspect of this classification system[25-26] (Fig. 4). Combined MG/MH devices accentuate the negative attributes of joint medialization and have been shown to require subscapularis repair in order to maintain stability.[47,48] Due to the amount of medialization, MG/MH designs are discouraged in the clinical setting of an uncorrected glenoid deformity as a result of preoperative glenoid bone erosion.[41,42,44] In such cases, bone graft may be required behind the glenoid with a MG/MH prosthesis to convert it to a LG/MH design configuration.[27,41,44] A LG/MH device can utilize its more lateral glenoid position with a more medial humeral position to better position the joint line to tension the residual rotator cuff and improve deltoid wrapping.[22,25-27,29] Since the overall construct is relatively lateralized, it can be more stable and may not require subscapularis repair for stability.[25,26,48,49]

However, the resulting deltoid abductor moment arm of the LG/MH construct is less than that of MG/LH designs due to its more lateralized CoR.[20,22-26] A MG/LH device can use the more lateral humeral position to compensate for the relative joint medialization caused by the thinner MG, thereby better tensioning the residual rotator cuff, better restoring deltoid wrapping, and further increasing the deltoid abductor moment arms.[22,25-27] The more lateral humeral position of the MG/LH device can also be configured to have a reduced scapular notching rate relative to MG/MH designs.[25,26,32,33,50,51] A fourth potential rTSA combination is the LG/LH design; the clinical results of this configuration have not yet been reported. Theoretically, it can achieve the same (or potentially better) residual rotator cuff tensioning and deltoid wrapping as a function of its lateral humeral

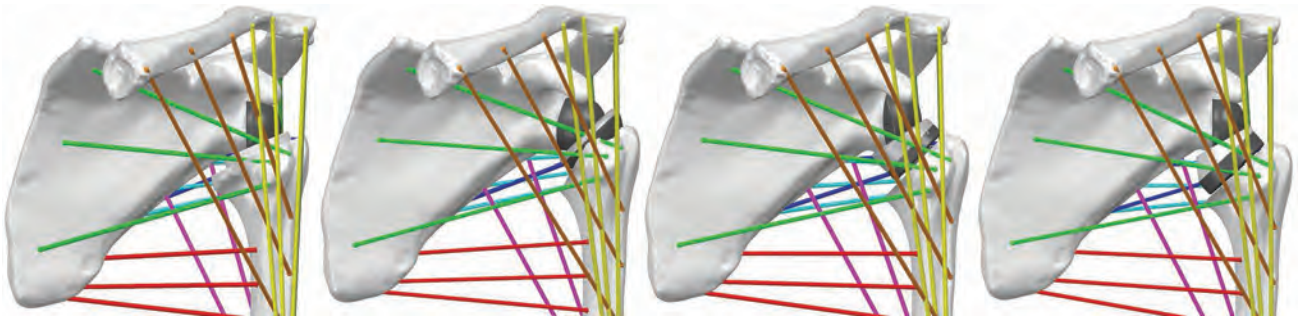

Figure 5 Representative images of the computer muscle model, from left to right: 36 mm Grammont MG/MH, 32 mm RSP® LG/MH, 38 mm Equinoxe® MG/LH, and 36 mm Ascend® MG/LH.

38 mm Equinoxe®, 5 mm tray (MG/LH)	27.1 mm	4.5 mm	5.7 mm	38.4 mm

placement; however, it will have inherently shorter deltoid abductor moment arms than MG/LH designs (due to its more lateral CoR) and also may place the shoulder muscles under too much tension. As a result of this most lateral configuration, perhaps the ideal clinical application for a LG/LH designs would be patients with severe glenoid bone erosion.

Illustrating Example

To simulate the combined impact of each of these design characteristics and rTSA prosthesis configurations on joint position, a 3D computer muscle model is presented (Fig. 5). This model and method have been previously utilized to quantify the impact of different prosthetic designs, glenoid bone deformities, humeral implantation techniques, and glenoid implantation techniques on muscle lengths and deltoid wrapping.[21,22,24,27,32,33,42,51] Furthermore, given the modularity of newer humeral prosthesis designs (which have multiple options for humeral neck angle or multiple offsets with eccentric trays), it is important for the orthopaedic surgeon utilizing these devices to understand the biomechanical consequences of these different implant positions and orientations. To illustrate these concepts, the 3D muscle model compared the Grammont Delta III (MG/MH), the DJO RSP® (LG/MH), the BIO-RSA® (LG/MH), the Exactech Equinoxe® (MG/LH; 0 and 5 mm humeral tray thicknesses), and the Tornier Ascend® (MG/LH; non-offset, ± 1.5 mm, and ± 3.5 mm offset) to quantify how each device impacted the muscle lengths of eight different shoulder

muscles during three different motions (abduction in the scapular plane, internal rotation with the arm at the side, and external rotation with the arm at the side). To standardize and allow for a direct comparison, each glenoid device was implanted identically with the baseplate aligned with the inferior glenoid rim in 0° tilt, and each humeral component was implanted in 20° retroversion.

Table 2 presents how the CoR and humeral position change for each prosthesis design relative to the native anatomic shoulder. Table 1 demonstrates that all MG designs are associated with a 27 mm to 28 mm medial shift in the CoR, while the LG designs are associated with only a 19 mm to 20 mm medial shift relative to the native CoR position of this computer model. Similarly, the MG/MH design was associated with the most medial humeral configuration with a 20 mm medial shift, while the LG/MH designs only medialize the humerus by 12 mm, and the (non-offset) MG/LH designs only medialize the humerus by 9 mm to 11 mm, relative to the normal anatomic relationship. Comparing the offset tray configurations demonstrates that the humerus can

be further medially and inferiorly shifted by nearly 5 mm, depending upon the direction of tray offset, compounding deltoid lengthening issues. Similarly, using a 5 mm thicker humeral tray and liner (as is customary in revisions or instances of joint laxity) results in approximately 3.4 mm less medialization and 3.6 mm more inferior shift.

Table 3 presents the deltoid wrapping of each prosthesis design when the arm is at the side and also the average muscle lengths during scapular abduction. Similarly, Tables 4 and 5 present the average muscle lengths for each prosthesis design during internal and external rotation with the arm at the side, respectively. Tables 3, 4, and 5 demonstrate that all reverse shoulders elongate the deltoid and shorten the rotator cuff muscles. Additionally, Table 3 demonstrates that the more lateral the humeral component, the greater the deltoid wrapping and also the more anatomic rotator cuff muscle tensioning. Finally, Tables 4 and 5 demonstrate that there is a wide variety of deltoid elongation (14.7% to 22.0% for the middle deltoid) and also a wide range of rotator cuff muscle shortening (-36.9% to -16.0% with the teres minor).

Interestingly, when comparing the two MG/LH designs (both 145° humeral neck angles), the Ascend® inferiorly shifts the humerus by 4.6 mm more than the Equinoxe®, which is why the Ascend® tensions the deltoid by more than 120% for all but one tray configuration. In fact, the deltoid tensioning with the Ascend® more closely resembles that of the Equinoxe® with a +5 mm humeral tray, which is used in less than 20% of clinical situations. The Ascend® also medially shifts the humerus by 2.7 mm more than the Equinoxe®, which is why the Ascend® is associated with less deltoid wrapping for all tray configurations and also tensions the rotator cuff less than the Equinoxe® in all tray configurations. These results demonstrate that subtle differences in glenoid and humeral design parameters combined result in fairly significant biomechanical changes. Furthermore, even with increased modularity, rTSA designs do not appear optimized; future work should attempt to conceive prosthesis parameters which elongate the deltoid less while better tensioning the rotator cuff muscles, each closer to its anatomic tension.

New Applications and Future Classification Refinements

The Grammont reverse shoulder prosthesis utilized a glenosphere in which the thickness was equal to its spherical radius to position the CoR on the glenoid face. In doing so, it increased the deltoid abductor moment arms and improved deltoid efficiency.[52] rTSA prosthesis designs will continue to evolve to further improve deltoid efficiency; one such method is to utilize a glenosphere in which the thickness is less than half its radius, such as the Equinoxe® 46 x 21 mm CoR glenosphere, which has been shown to have up to a 40% increase in the deltoid efficiency relative to other commercially available devices.[52] Such a glenoid design could be termed an extra medial glenoid (XMG) and be used with MH or LH designs. It is also possible to posteriorly shift the humerus by offsetting the humeral tray of an onset LH design; doing so increases the length of the external rotation moment arms and better tensions the posterior rotator cuff.[21] This design could be termed a medial glenoid and posterolateral humerus (MG/PLH). Finally, as rTSA are increasingly used in revisions and clinical scenarios with deficient proximal humeral bone, humeral reconstruction prostheses can be utilized to allow for greater than anatomic lateralization (Fig. 6). Increasing humeral lateralization can further increase deltoid wrapping and improve stability in the presence of both bone and soft-tissue deficiency and avoid the use of costly allograft-prosthetic composites that have the potential to resorb. This design could be termed a medial glenoid and extra lateral humerus (MG/XLH).

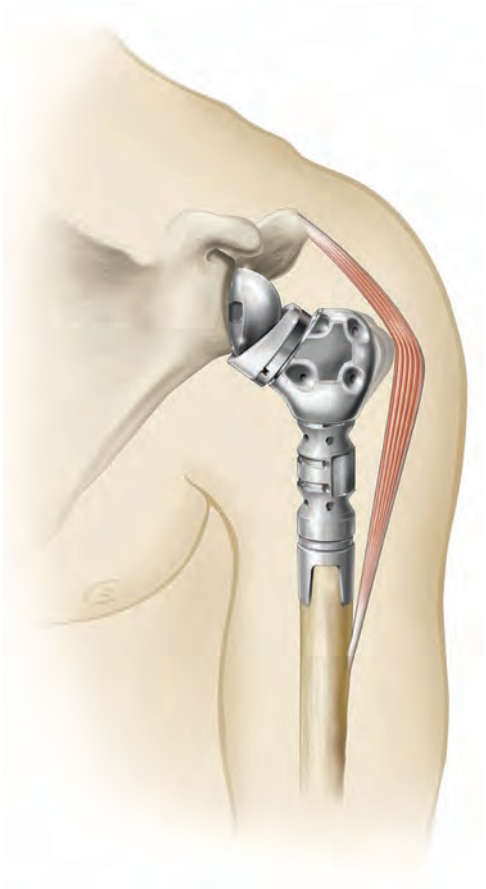

Figure 6 Extra humeral lateralization to increase deltoid wrapping in the clinical scenario of proximal humeral bone loss using the Equinoxe® Reconstruction Humeral Prosthesis (Exactech, Inc., Gainesville, FL).

Conclusion

Orthopaedic surgeons have numerous decisions to make when addressing the various bone and soft tissue challenges associated with the growing and different indications for rTSA. Until now, there has not been any complete or unifying nomenclature for describing the different prosthesis design characteristics of the reverse shoulder. This

classification system[25,26] is both descriptively helpful and clinically useful as it can discern quantifiable differences in prosthesis design types and can be used to guide surgeons in their choice of an rTSA.

The Impact of Posterior Wear on Reverse Shoulder Glenoid Fixation

Abstract

Introduction: Achieving glenoid fixation with posterior bone loss can be challenging. The purpose of this study was to quantify the impact of two different sizes of posterior glenoid defects (10° and 20°) on reverse shoulder arthroplasty (rTSA) glenoid baseplate fixation and determine if utilizing different sizes of posterior augmented baseplates (8° and 16°) with off-axis reaming provides comparable fixation to using a standard baseplate with different amounts of eccentric reaming.

Methods: We quantified the impact of 10° and 20° posterior glenoid defects on rTSA baseplate fixation in composite scapulae using the ASTM F2028-14 rTSA glenoid loosening test method. Forty-two total implants (N = 7 for each size defect and for each type of baseplate) were tested at 750 N for 10,000 cycles. Baseplate displacement was measured before and after cyclic loading in the superior-inferior and anterior-posterior directions. Statistical analysis was performed with a two-tailed unpaired Student's t-test (significance defined as $p < 0.05$) to compare prosthesis displacements relative to each scapula (10° and 20° posterior defects for each type of baseplate versus the non-defect control) before and after cyclic loading.

Results: All glenoid baseplates remained well-fixed after cyclic loading in composite scapulae without a defect and in scapulae with posterior defects. Increased pre- and post-cyclic displacement was observed with increased posterior defect size and differences in displacement were observed between standard and augmented baseplates. Augmented baseplates were observed to remove significantly less bone than standard baseplates when correcting posterior defects, regardless of size.

Discussion: Both standard baseplates with eccentric reaming and two different sizes of augmented baseplates with off-axis reaming successfully maintained fixation following cyclic loading in composite scapula with corrected 10° and 20° posterior glenoid defects. Augmented glenoids may be more advantageous long-term from a fixation perspective as they preserve more subchondral glenoid bone due to the minimal reaming occurring by the off-axis method. Mid and long-term clinical follow-up comparisons of outcomes are necessary between these two techniques.

Glenoid bone loss with pathological retroversion is commonly seen in patients with severe glenohumeral arthritis resulting from many different underlying etiologies, most commonly late-stage osteoarthritis. Loss of glenoid bone stock and abnormal bony architecture necessitate reconstruction during total shoulder arthroplasty (TSA), whether with an anatomic (aTSA) or reverse (rTSA) total shoulder arthroplasty prosthetic design. Glenoid reconstruction requires meticulous preoperative planning with quantitative measurements to determine the extent and location of the correction or augmentation required in Type B and C glenoids according to the Walch classification.[1]

Preoperative computerized tomography (CT) scans play an important role in evaluating patients preoperatively for a TSA, as plain radiographs and intraoperative visualization are not accurate or reliable. A CT scan with 3D reconstruction provides an accurate depiction of the bony anatomy, the extent of the patient's bone loss, and the need for modifica-

Friedman R, Stroud N, Glattke K, Flurin P-H, Wright TW, Zuckerman JD, Roche CP. The impact of posterior wear on reverse shoulder glenoid fixation. Bull Hosp Jt Dis. 2015;73(Suppl 1):S15-20.

tion of the surgical procedure. Various techniques have been described to quantify the amount of bone loss.[2]

For the long-term success of a TSA, excessive retroversion needs to be corrected at the time of the arthroplasty. If not, there are significant consequences that will increase the risk of glenoid component failure. Previous studies have shown that the stresses at the bone cement interface increase with retroversion, thereby increasing the rate of aseptic loosening.[3-5] Also, there are increased contact pressures that can wear the glenoid component polyethylene and also increased implant micromotion with increased retroversion, all of which can contribute to aseptic loosening as well.[3-5]

Glenoid reconstruction for severe bone loss with increased retroversion in the face of severe arthritis can be challenging. Previous surgical techniques to correct the retroversion have included eccentric reaming of the high anterior side, but this can result in loss of valuable glenoid bone stock, downsizing of the glenoid component as it is medialized, and loss of subchondral bone that can impact long-term glenoid component fixation. Posterior bone grafting can also be performed, but it is technically very difficult, and the presence of cement may affect osteointegration; the graft is subject to resorption and loosening over time as well.[5-12]

A posterior augmented component with off-axis reaming can be used to correct excessive glenoid retroversion in both aTSA and rTSA.[8-12,13] Advantages over current methods include decreasing the amount of reaming, thereby saving valuable glenoid bone stock; eliminating the need for bone grafting; better restoring the native joint line to rebalance the joint; and converting shear forces to compressive forces down the glenoid neck, thereby protecting the bone cement and bone prosthesis interfaces. Practical considerations exist for correcting excessive retroversion and enabling the surgeon to overcome technical challenges to do the arthroplasty correctly. In these situations, the glenoid faces away from the surgeon and makes the procedure technical very difficult to perform. It is also more difficult to seat the glenosphere on the baseplate with excessive retroversion, so correcting this helps to ensure a well-done arthroplasty.

Some have suggested that rTSA be used in cases of severe retroversion combined with excessive posterior subluxation, the B2 glenoid according to the Walch classification.[14] To correct the excessive retroversion, either eccentric reaming or off-axis reaming with an augmented glenoid baseplate can be used. rTSA, as compared to aTSA, has some potential to have better mid- and long-term outcomes in patients with severe posterior wear because the conforming reverse articulation may provide better joint stability for patients with a posterior subluxed humeral head.[14] Additionally, the uncemented metal rTSA baseplate with supplemental screw fixation may provide better long-term glenoid fixation in patients with severe posterior wear than a cemented aTSA glenoid due to the need to eccentrically ream the glenoid to correct the deformity.[5-7,14]

We conducted this study to quantify the impact of two sizes of B2 posterior glenoid defects (10° and 20°) on rTSA glenoid baseplate fixation in a composite scapula model using the recently approved ASTM F2028-14 reverse shoulder glenoid loosening test method.[15] The aim of this study is two-fold: 1. to quantify the impact of posterior glenoid defect size on rTSA glenoid baseplate fixation and 2. to determine if utilizing different sizes of posterior augmented baseplates with off-axis reaming provides comparable fixation to using a standard baseplate with different amounts of eccentric reaming.

Materials and Methods

Forty-two 38 mm rTSA implants (Equinoxe®, Exactech, Inc.) were tested in a fourth generation composite, dual density scapula (Pacific Research, Inc., Vashon, WA) with a 1.63 g/cm^3 "cortical" shell and a 0.27 g/cm^3 "cancellous" interior structure. This substrate provides a representative substitute for the density, strength, and modulus of glenoid cortical and cancellous bone in the recipient patient population for rTSA.[16-19] Posterior biconcave defects of 10° and 20° were reamed into the composite scapulae with the aid of a cannulated reamer and custom jig. The 10° and 20° posterior defects were intended to simulate two different sizes of B2 glenoids, which may be treated clinically with rTSA.[1,14]

Baseplate fixation in the 10° and 20° posterior glenoid defect scapulae were assessed using both standard rTSA glenoid baseplates with eccentric reaming (N = 7 for each size defect) and using 8° posterior augment glenoid baseplates with off-axis reaming (N = 7 for each size defect) (Fig. 1).

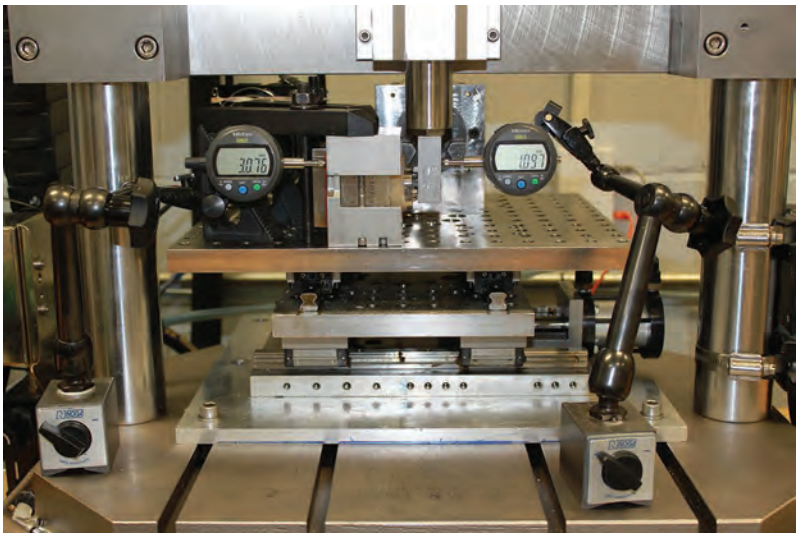

Figure 2 Representative image of the rTSA glenoid loosening displacement test.

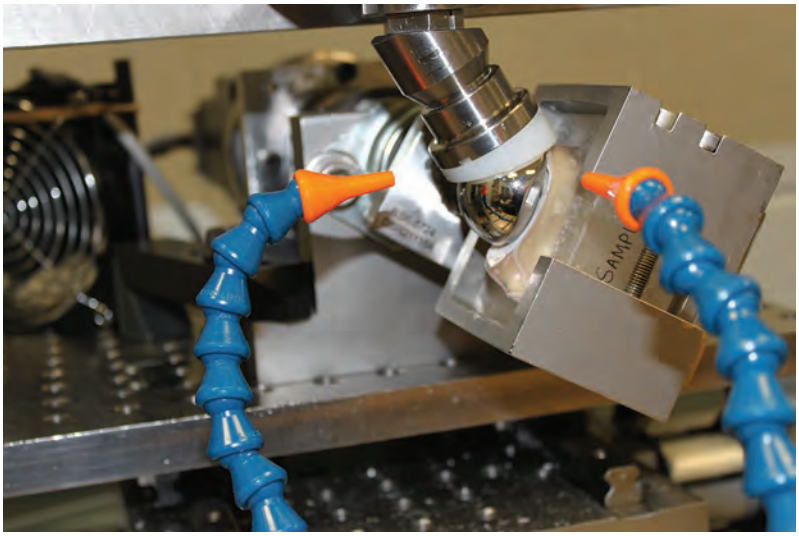

Figure 3 Representative image of the rTSA glenoid loosening cyclic test.

Sixteen degrees posterior augment glenoid baseplates were also tested in the 20° posterior defect scapulae (N = 7). All devices were compared to composite scapulae without a glenoid defect (N = 7) before and after cyclic loading, which functions as the control in the study. Initial fixation of each glenoid baseplate was achieved using four (one superior, one inferior, one anterior, and one posterior), 4.5 mm x 30 mm diameter poly-axial locking compression screws and a press-fit tapered cage peg. After assembly, the composite scapulae were cut and potted with bone cement.

This study was conducted according to ASTM F2028-14 in two phases.[15] This rTSA glenoid loosening test method has been used previously to identify differences in fixation between screw configurations,[20] medialized and lateralized center of rotation,[21-23] glenoid baseplate designs,[22-24] scapular defects and wear patterns,[13,25] and different densities of substrates.[20,23,24] The first phase was the displacement test (Fig. 2). It measured the fixation of the rTSA glenoid baseplate in the composite scapula before and after the application of 10,000 cycles of dynamic loading for 55° at 0.5 Hz. In the displacement test, the axial test machine (Instron Corp. Norwood, Mass., resolution of 1 micron) and three digital indicators (Mitutoyo, Japan, resolution of 1 micron) quantified the glenoid baseplate displacement relative to the composite scapula as a compressive (50 N) and shear (357 N) load was applied. The compressive axial load was applied perpendicular to the reverse glenoid baseplate, and the shear load was applied parallel to the face of the glenoid baseplate along its superior-inferior (SI) axis and then repeated along the anterior-posterior (AP) axis. Dial indicators were used to subtract out any compliance of the test construct. The second phase is the cyclic test. The cyclic test simulates the primary motion of rTSA; that is, the abduction motion generated by the deltoid. The humeral liner and scapulae with rTSA baseplate and glenosphere were positioned in the biaxial testing apparatus and aligned along the SI axis of the glenoid baseplate (Fig. 3). A 750 N axial load was constantly applied through the center of the humeral liner as the scapulae with rTSA baseplate and glenosphere were rotated about the humeral component with a stepper motor to create a sinusoidal angular displacement profile encompassing an arc of 55° at 0.5 Hz for 10,000 cycles. The components

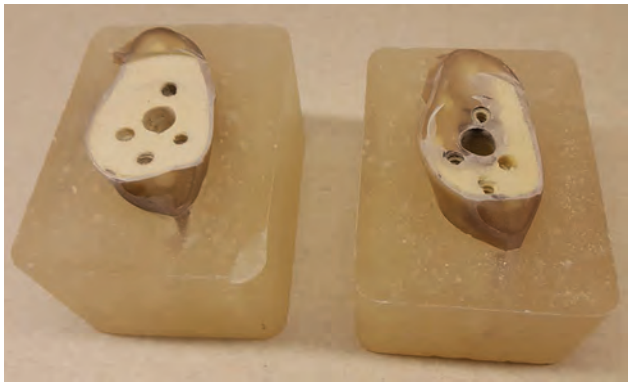

Figure 4 Representative images after testing of the composite scapula glenoid with a 20° posterior glenoid defect. Left image: bone removed using the standard baseplate with eccentric reaming to correct defect. Right image: bone removed using the 16° posterior augmented baseplate with off-axis reaming to correct defect.

were cooled with a continuous jet of air with no lubrication. Statistical analysis was performed by means of a two-tailed unpaired Student's t-test (significance defined as $p < 0.05$) to compare prosthesis displacements relative to each scapula (10° and 20° posterior defects for each type of baseplate vs. the non-defect control) before and after cyclic loading.

Results

All rTSA glenoid baseplates remained well-fixed after cyclic loading in composite scapulae without a defect and with each 10° and 20° posterior glenoid defects, regardless of baseplate type or reaming method. Augmented glenoid baseplates removed less of the composite bone when correcting each size defect, with 16° baseplates removing the least bone when correcting the largest defect (Fig. 4). Table 1 presents the average pre- and post-cyclic glenoid baseplate displacement in scapulae with 10° posterior glenoid defects. As presented, both standard baseplates with 10° eccentric reaming and 8° posterior augment baseplates with off-axis reaming were associated with significantly larger SI and AP post-cyclic displacement than the standard baseplate in composite scapula without a defect. Additionally, 8° posterior augment baseplates in 10° defect composite scapulae were associated with significantly less SI post-cyclic displacement than standard baseplates with 10° eccentric reaming, though no difference was noted in post-cyclic AP displacement.

Table 2 presents the average pre- and post-cyclic glenoid baseplate displacement in scapulae with 20° posterior glenoid defects. As presented, each of the standard baseplates with 20° eccentric reaming, 8° posterior augment baseplates with off-axis reaming, and 16° posterior augment baseplates with off-axis reaming were associated with significantly larger SI and AP post-cyclic displacement than the standard baseplate in composite without a defect. Additionally, standard baseplates in 20° defect composite scapulae were associated with significantly less AP post-cyclic displacement than both the 8° and 16° posterior augment baseplates and also less SI post-cyclic displacement than 16° posterior augment baseplates. Finally, 8° posterior augment baseplates in 20° defect composite scapulae were associated with significantly less SI post-cyclic displacement than 16° posterior augment baseplates.

Discussion

The results of this study demonstrate that either standard baseplates with eccentric reaming or augmented baseplates with off-axis reaming can be used to maintain rTSA glenoid fixation, even in scapulae with very large posterior glenoid defects. However, using rTSA in the scapula with posterior glenoid defects generally increased the pre- and post-cyclic baseplate displacement relative to the non-defect control, regardless of baseplate type or reaming method, with larger size defects associated with greater increases in pre- and post-cyclic displacement.

Some differences in fixation were noted between standard and augmented baseplates. For 10° posterior defects, augmented baseplates were associated with significantly less SI post-cyclic displacement than standard baseplates, though no difference was noted in AP post-cyclic displacement. However, for larger 20° posterior defects, standard baseplates were associated with significantly less AP post-cyclic displacement than both the 8° and 16° posterior augment baseplates and also less SI post-cyclic displacement than 16° posterior augment baseplates. Finally, augmented glenoid baseplates with off-axis reaming conserved more glenoid bone than standard baseplates with eccentric reaming, with more bone conserved in larger size defects.

Obtaining fixation with TSA in scapula with eroded glenoid can be challenging. When the orthopaedic surgeon is faced with posterior glenoid defects up to 10°, both standard

baseplates with eccentric reaming and augmented baseplates with off-axis reaming can effectively maintain rTSA glenoid fixation following correction of the defect. The results of this study and others[8-10,13] also demonstrate that augmented glenoids remove less bone when correcting defects. In doing so, augmented glenoids better maintain the native joint line, which has the potential to better restore anatomic muscle lengths, as demonstrated previously with augmented aTSA glenoid components when used in different sizes of posterior glenoid defects.[10]

However, the results of this study are less clear for orthopaedic surgeons when faced with posterior glenoid defects up to 20°. Standard baseplates with eccentric reaming were associated with significantly less displacement than augmented baseplates in these very large defects; although, every standard and augmented baseplate tested with this glenoid loosening methodology completed the cyclic test without failure. This glenoid loosening methodology has previously been utilized to test six different commercially available designs, and three of those six failed to pass this cyclic test when evaluated in low density polyurethane blocks without any defects.[23,24] Recent mid and long-term clinical follow-ups from Walch and coworkers has demonstrated significant increases in radiographic loosening and subsidence rates in aTSA patients when the glenoid was reamed more aggressively as compared to those that were not.[26,27] Several other studies have recommended upper limits (e.g., 10° to 15°) on the amount of retroversion that can be corrected with eccentric reaming alone.[6,7,28] Thus, the significantly lower displacements observed with the standard baseplate in these very large defects may be offset clinically by the substantial removal of bone by eccentric reaming. Augmented glenoids may be more advantageous long-term from a fixation perspective as they preserve more subchondral glenoid bone due to the minimal reaming occurring by the off-axis method. Mid and long-term clinical follow-up comparisons of outcomes are necessary between these two techniques.

This rTSA baseplate fixation study in posterior glenoid defects has some limitations. First, we used a composite scapulae model rather than matched pair cadaveric specimens to reduce variables related to cortical and cancellous density and bone thickness. Additionally, we desired identical morphology to ensure that the created posterior glenoid defects were the same in each tested specimen. Second, this model only evaluated initial fixation and does not simulate the impact of any osseous integration; it is unknown whether implant osteointegration in the clinical situation may mitigate early fixation vulnerabilities. Finally, this study does not evaluate different screw patterns or the impact of using additional screws. The baseplate utilized in this test permits use of up to six poly-axial locking compression screws, and the use of additional screws or different patterns of screws may improve fixation. Future work should investigate the ability of different implantation and positioning techniques, placement of additional screws, or utilizing different screw patterns to mitigate any early fixation vulnerabilities in this posterior glenoid defect model.

Conclusions

This study demonstrates that both standard baseplates with eccentric reaming and two different sizes of augmented baseplates with off-axis reaming successfully maintained fixation following cyclic loading in composite scapulae with corrected 10° and 20° posterior glenoid defects. Increased pre- and post-cyclic displacement was observed with increased posterior defect size, and differences in displacement were observed between standard and augmented baseplates. Augmented glenoid baseplates with off-axis reaming may be more advantageous long-term from a fixation perspective as they preserve more subchondral glenoid bone due to the minimal reaming occurring by the off-axis method, which was observed to remove significantly less

bone than the eccentric reaming method to correct the defect. Clinical follow-up comparisons of outcomes between these techniques are necessary.

Role of Subscapularis Repair on Muscle Force Requirements with Reverse Shoulder Arthroplasty

Matthew L. Hansen, M.D., Aniruddh Nayak, M.S., Madusudanan Sathia Narayanan, Ph.D., Kellen Worhacz, B.S., Richard Stowell, M.D., Marc C. Jacofsky, Ph.D., and Christopher P. Roche, M.S., M.B.A.

Abstract

Concomitant repair of the subscapularis with reverse shoulder arthroplasty (rTSA) is controversial. To evaluate the biomechanical impact of subscapularis repair with rTSA, a cadaveric shoulder controller quantified the muscle forces required to elevate the arm during scapular abduction with the elbow flexed at 90°. The results of this study demonstrate that concomitant subscapularis repair with rTSA creates a biomechanically unfavorable condition during arm elevation. Specifically, repair of the subscapularis significantly increased the force required by the deltoid and posterior rotator cuff and also significantly increased the joint reaction force relative to when the subscapularis was not repaired. These results also demonstrated that both the 42 mm Grammont and 42 mm Equinoxe® rTSA prostheses significantly decreased the mean force required by the posterior rotator cuff and also significantly decreased the mean joint reaction force over the range of motion relative to the native joint with a rotator cuff tear (supraspinatus). As the posterior rotator cuff is often compromised in patients undergoing rTSA, patients may not be able to sustain these elevated forces in the infraspinatus and teres minor required to counteract the adduction and internal rotation moments generated by the subscapularis during activities of daily living. Similarly, the elevated posterior deltoid force and joint reaction loads could be deleterious to the long-term life of the prosthesis and can also increase the risk of loosening and fractures. For all these reasons, rTSA functional outcomes may be compromised if the subscapularis is repaired.

Reverse total shoulder arthroplasty (rTSA) has found great success over the last decade, evolving from a salvage procedure used in difficult situations to a more mainstream procedure. This procedure has been widely accepted to treat conditions, such as massive rotator cuff tears, cuff tear arthropathy, and proximal humerus fractures.[1-9] Distinct from anatomic total shoulder arthroplasty (aTSA), rTSA is inherently more constrained as a result of its conforming articular geometry and inverted anatomic concavities. Specifically, the rTSA prosthesis has a convex glenoid and concave humerus that function as a fixed fulcrum articulation to prevent superior humeral migration. While this inverted arrangement is common to all rTSA prosthesis designs, significant inter-manufacturer variability exists, particularly as it relates to the position of the joint center of rotation (CoR) and the position of the humerus.[10-14] Given the variety of different rTSA prosthesis design configurations available in the worldwide marketplace, the anatomic shoulder can be altered by rTSA as follows: 1. 15 mm to 30 mm medial shift in the CoR, 2. a 25 mm to 40 mm distal shift in the position of the humerus, and 3. a 10 mm to 25 mm medial shift in the position of the humerus.[12] Such joint configuration changes modify the normal anatomic relationships between the origins and insertions of the shoulder muscles, altering their resting lengths, operational envelopes, and moment arms.[10-24] These geometric changes have been demonstrated to improve deltoid efficiency[10-22]; however, their effect on the rotator cuff is not as clearly known.[12,23-25]

Of particular interest is the effect of different rTSA prosthesis designs on the performance of the subscapularis muscle. Controversy exists surrounding concomitant repair

of the subscapularis with rTSA. It has been reported that repair of the subscapularis is necessary to ensure joint stability,[26] and indeed orthopaedic surgeons are very accustomed to repairing the subscapularis in aTSA. However, this muscle has relatively little potential for increased excursion, and the integrity of these repairs after rTSA is questionable given the typical involvement in the pathology. Prosthesis designs that are associated with a more medial humeral position have been shown to have greater risk for instability if the subscapularis is not repaired,[10,11,25,26] whereas prosthesis designs that position the humerus more laterally have been shown to not have any increased risk of instability when the subscapularis is not repaired and are associated with more anatomic muscle tensioning.[10-12,25,27]

The native subscapularis muscle is known to operate in a biphasic manner. The superior portion inserts on the lesser tuberosity proximal to the CoR causing abduction, whereas the inferior portion inserts distal to the CoR causing adduction.[25,28-30] These two portions of the subscapularis also have separate innervation.[31-33] By shifting the position of the humerus in an inferior-medial position with rTSA, the proximal subscapularis is generally shifted below the CoR, converting it into an adductor for most of the range of motion (ROM). Its action as an adductor would, therefore, counteract the work of the deltoid, increasing its force required to elevate the arm and also increasing the overall joint reaction force, which may be deleterious to the long-term life of the device.[10,11,25]

It is hypothesized that concomitant subscapularis repair will increase the deltoid force required for abduction, the posterior rotator cuff required for external rotation, and the overall joint reaction force with rTSA. To that end, the purpose of this cadaveric shoulder controller study is to quantify the different muscle forces required to abduct the arm in the scapular plane from 20° to 70° when the elbow is flexed at 90° and compare in three different scenarios: 1. supraspinatus tear in the native anatomic shoulder, 2. two different RTSA prostheses designs, and 3. subscapularis repair with rTSA.

Methodology

A second-generation cadaveric shoulder controller that utilizes simulated neuromuscular control was used for this study. This shoulder controller is similar to that described by Hansen and coworkers with upgrades and a greater refresh rate for the control loop.[34] Stepper motors (Industrial Devices Corporation, Salem, New Hampshire) actuate cables that are attached to the rotator cuff tendons and deltoid tuberosity. Force transducers measure the tension developed in each cable as active closed-loop position, and orientation control algorithms control each motor. This active controller allows the cadaveric model to simulate *in vivo* glenohumeral kinematics and muscle loads during various motions. As presently configured, the controller utilizes active optical markers (Northern Digital, Inc., Waterloo, Ontario, Canada) to track motion, and a six-axis load cell measures the resultant joint reaction force at the glenohumeral joint. Specifically, the cable and eyelet configurations simulate the three heads of the deltoid (middle, posterior, anterior), the supraspinatus, the subscapularis, the pectoralis major, the infraspinatus, and teres minor.

Figure 1 Representative image of the surrogate deltoid model used with the cadaveric shoulder controller.

To simulate more-physiologic joint compression and induce more-anatomic deltoid wrapping around the greater tuberosity,[10-12,35-37] a deltoid surrogate model was created. Deltoid wrapping has also been demonstrated to vary with different rTSA prosthesis designs and implantation techniques.[10-12] This muscle model was made from VytaFlex® 50 Liquid Urethane Rubber (Smooth-On, Inc.) and physically connected to three cables through three polyethylene tubes embedded within, to route the muscle lines for the anterior, middle, and posterior deltoid to the respective eyelets as shown during the ROM (Fig. 1).

Five male cadaveric full upper extremity specimens (age: 65.6 ± 6.3 years) were selected with similar height and BMI (height: 71.6 ± 2.0 inches; BMI: 30.2 ± 9.8) to ensure similar anthropometrics and tested in scapular plane abduction without any artificial external constraints from 20° to 70° with the full mass of the upper extremity. The tests were performed with the elbow flexed at 90° to simulate the passive internal rotation gravitational torque associated with many activities of daily living (ADL). Five conditions were tested in 5° increments over the ROM: 1. native shoulder, 2. native shoulder with a supraspinatus tear, 3. 42 mm Equinoxe® rTSA with subscapularis repair (as simulated by a constant 15 N subscapularis force which was previously deemed to be the minimum force necessary to maintain a stable joint using this controller[38,39]), 4. 42 mm Equinoxe® rTSA without subscapularis repair, and 5. a 42 mm Delta III Grammont rTSA without subscapularis repair. Five trials were performed for each condition and each trial was averaged. A Student's two-tailed unpaired t-test was conducted on the mean muscle forces over the ROM for each condition where $p < 0.05$ deemed significance.

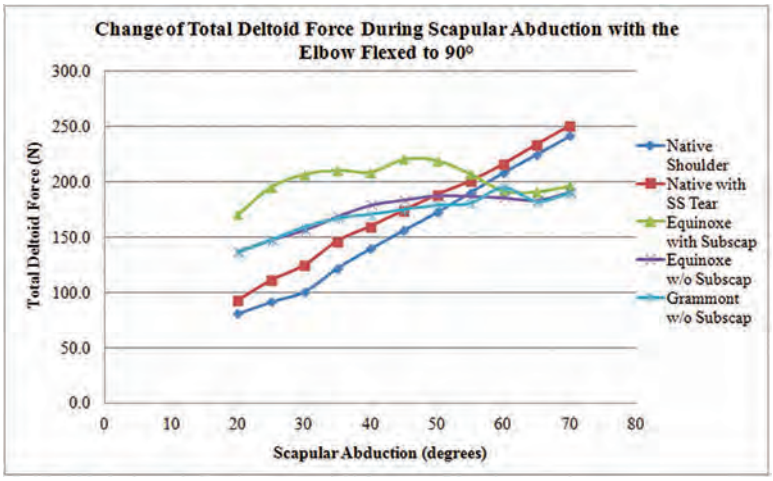

Figure 2 Comparison of deltoid force requirements during scapular abduction with the elbow flexed to 90°.

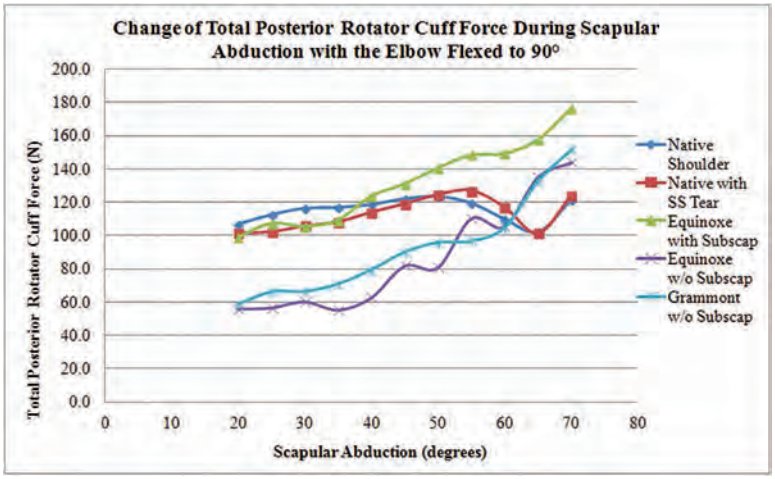

Figure 3 Comparison of posterior rotator cuff force requirements during scapular abduction with the elbow flexed to 90°.

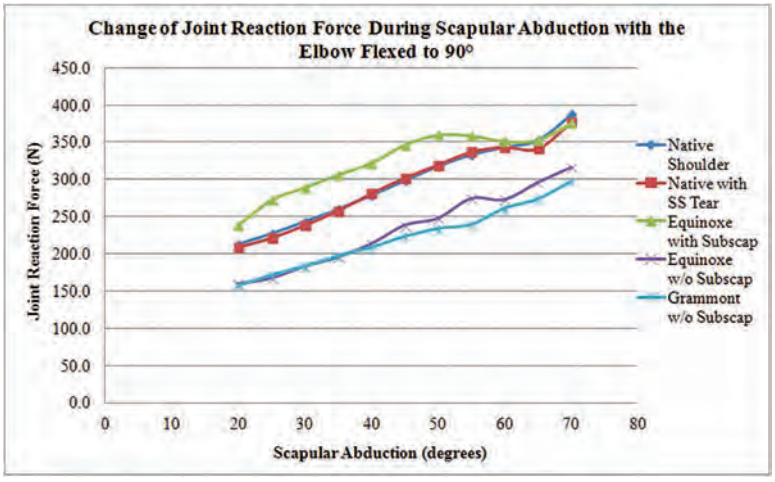

Figure 4 Comparison of joint reaction force requirements during scapular abduction with the elbow flexed to 90°.

Results

Both the 42 mm Grammont and 42 mm Equinoxe® rTSA prostheses significantly decreased the mean force required by the infraspinatus, teres minor, total posterior cuff, and pectoralis major muscles and also significantly decreased the mean joint reaction force during scapular abduction with the elbow flexed to 90° relative to the native joint with a rotator cuff tear (supraspinatus), (Table 1). Specifically, the mean force required by the posterior rotator cuff was observed to decrease by 18.7% to 23.8%, and the mean joint reaction force decreased by 24.2% to 20.4% for the 42 mm Grammont and 42 mm Equinoxe® prostheses, respectively. No difference in the mean muscle force requirements were noted between the two rTSA prosthesis designs without subscapularis repair, and no difference was noted between the native shoulder with and without a supraspinatus tear.

Repair of the subscapularis with rTSA significantly increased the force required by the posterior deltoid, total deltoid, infraspinatus, teres minor, total posterior cuff, and pectoralis major muscles and also significantly increased the mean joint reaction force during scapular abduction with the elbow flexed to 90° relative to when the subscapularis was not repaired (Table 1). Specifically when the subscapularis was repaired using the 42 mm Equinoxe®, the mean force required by the posterior deltoid and posterior rotator cuff increased by 31.7% to 34.4%, respectively, during the ROM. Additionally, this increased deltoid force (Fig. 2), posterior cuff force (Fig. 3), and joint reaction force (Fig. 4) were most pronounced between 20° and 60° of scapular abduction, though these increases persisted throughout the ROM.

Discussion

The results of this cadaveric shoulder controller study demonstrate that repair of the subscapularis with rTSA significantly increased the force required by the posterior deltoid and posterior rotator cuff to elevate the arm when the elbow is flexed and also significantly increased the joint reaction force relative to when the subscapularis is not repaired. These results also demonstrate that both the 42 mm Grammont and 42 mm Equinoxe® rTSA prostheses significantly decreased the mean force required by the posterior rotator cuff and also significantly decreased the mean joint reaction force over the ROM relative to the native joint with a rotator cuff tear (supraspinatus). No differences in the mean muscle force requirements were noted between the two rTSA prosthesis designs without subscapularis repair, and no difference was noted between the native shoulder with and without a supraspinatus tear.

These results provide support for the hypothesis that rTSA with concomitant subscapularis repair creates a biomechanically unfavorable condition during arm elevation. By shifting the subscapularis insertion in the inferior-medial direction below the CoR, the subscapularis converts from being primarily an abductor to being primarily an adductor throughout the ROM, counteracting the abduction torque generated by the deltoid. This explains the observations in this study that more force was required by the deltoid when the subscapularis was repaired as opposed to when the subscapularis was not repaired.

We chose to perform the study with the cadaver elbow fixed in 90° of flexion to better simulate functional arm positions, such as those that are required by activities of daily living (ADL). This may be a more realistic scenario because elbow flexion is required for most ADL, such as washing hair, brushing teeth, drinking from a cup, etc. As the shoulder is abducted while the elbow is flexed, shoulder internal rotation torque is produced by gravity acting on the forearm and hand. Clinically, this internal rotation torque is manifest as hornblower's sign and is associated with posterior rotator cuff deficiency.[40] Such patients typically exhibit shoulder abduction but have difficulty with ADL that require bringing the hand near the head because their shoulder falls into internal rotation. Experimental setups that test the shoulder while the elbow is extended do not have the same magnitude of internal rotation torque. Because the posterior rotator cuff and posterior deltoid produce an external rotation torque at the shoulder, these muscles oppose the internal rotation torque caused by gravity.

Clinical improvement after rTSA is greater if there is some remaining functional posterior rotator cuff or if additional external rotation torque is provided by other means, such as a latissimus dorsi muscle transfer to the posterior proximal humerus.[41-44] If the subscapularis is intact and also producing internal rotation torque, the total magnitude of internal rotation torque may be greater than can be overcome by the posterior cuff and the hornblower's sign and accompanying shoulder dysfunction may be worsened. This explains the observations in this study that more force was required by the posterior cuff when the subscapularis was repaired as opposed to when the subscapularis was not repaired. Furthermore, this study showed increased joint reaction force for the subscapularis repair condition. This increased force is a result of increased co-contraction of the subscapularis, the posterior cuff, and the posterior deltoid. Elevated joint reaction forces may increase polyethylene component wear and increase risk of aseptic glenoid loosening, acromial stress fractures, and deltoid fatigue. These results related to increased deltoid, posterior cuff, and joint reaction force with subscapularis repair provides support for avoiding subscapularis repair with rTSA.

Not repairing the subscapularis with rTSA contradicts the recommendation of Edwards and colleagues where it was reported that the instability rate increases when the subscapularis is not repaired with rTSA.[26] As previously explained by Routman and associates and others, repair of the subscapularis may be dependent on prosthesis design, where rTSA designs that medialize the humerus less may be more inherently stable due to improved deltoid wrapping and more anatomic muscle tensioning.[10-12,25] Indeed, Edwards and colleagues justification for subscapularis repair is to decrease dislocations rather than to improve external rotation strength.[26]

The two rTSA designs used in this study are fundamentally different.[10-14,45-47] The Grammont design shifts the glenoid (and CoR) medially and shifts the humerus medially. The Equinoxe® design also has a medial glenoid shift, but the design of the humeral component causes a lateral shift of the humerus compared to the native shoulder and the Grammont design. Because of the greater moment arm imparted to the deltoid with the Equinoxe® design, it was expected that less deltoid force would be required with this design. This effect has been observed in computer studies[13,14] but could not be demonstrated in this cadaveric shoulder controller study. However, both rTSA designs did show decreased deltoid force compared to the native shoulder with rotator cuff tear. This is consistent with expectations for rTSA. It should be noted that 42 mm sizes of each device were utilized in this study to simulate the use of rTSA in these relatively

large (height: 71.6 ± 2.0 inches; BMI: 30.2 ± 9.8) shoulder specimens; we recognize that shoulder surgeons often utilize smaller size reverse components but may use larger sizes in such larger shoulders to improve stability by increasing jump distance or reducing the risk of scapular impingement.[45-48] As the moment arms are similar between the 36 mm, 38 mm, and 42 mm sizes of each prosthesis tested and as each also positions the CoR and humerus similarly, we do not think that the use of larger size rTSA prostheses in this study in anyway limits our results to other sizes of these prosthesis designs.

As with other cadaver shoulder loading models, the main limitation of the study is that the set of muscle forces determined by the shoulder controller for each shoulder position is not unique. Other muscle force combinations may yield the same positions. Future work should utilize the shoulder controller to evaluate the role of subscapularis repair on multiple different rTSA prosthesis designs and determine if these observed biomechanical improvements are generalizable to all prosthesis designs.

Conclusions

Whether concomitant subscapularis repair should be performed during rTSA is controversial.[25-27] This cadaveric shoulder controller study provides biomechanical data that recommends avoiding the repair to reduce the forces required by the shoulder muscles during scapular abduction with the elbow flexed. Specifically, repairing the subscapularis significantly increased the force required by the posterior rotator cuff and posterior deltoid and also increased the overall joint reaction force relative to when the subscapularis was not repaired with rTSA. As the posterior rotator cuff is often compromised in patients undergoing rTSA, patients may not be able to sustain these elevated forces in the infraspinatus and teres minor required to counteract the adduction and internal rotation moments generated by the subscapularis during activities of daily living. Similarly, the elevated posterior deltoid force and joint reaction loads could be deleterious to the long-term life of the prosthesis and can also increase the risk of loosening and fractures. For all these reasons, rTSA functional outcomes may be compromised if the subscapularis is repaired.

Assessment of the Anatomic Neck as an Accurate Landmark for Humeral Head Resurfacing Implant Height Placement

Emmon J. Chen, M.S., Ryan Simovitch, M.D., Felix Savoie, M.D., and Curtis R. Noel, M.D.

Abstract

Introduction: Humeral head resurfacing has been described as a more anatomic replacement alternative for proximal humerus arthroplasties when compared to conventional stemmed implants. However, not all studies show that humeral head resurfacing is better at reproducing the proximal humeral anatomy with overstuffing of the joint being a common complication. The purpose of this study was to assess the use of the anatomic neck as a landmark for proper placement of humeral head replacements.

Methods: Sixty-six cadaveric shoulder CT scans were reconstructed using Mimics to create 3D models of the humerus. After 3D reconstruction, each bone model was analyzed in Rapidform to establish the anatomic neck plane, the humeral head average radius of curvature, and anatomic center of rotation (CoR) using a best fit sphere over the articular surface. Humeral head resurfacing implants (Equinoxe®, Exactech, Inc.) were assembled onto the 3D humeral models, selected by matching the closest implant size available with the anatomic radius of curvature. Implants were constrained to match the anatomic neck angle and version and were spaced 2 mm away from the anatomic neck. The 3D distances between the anatomic center of rotation and the implant CoR and the implanted head thickness deviations were measured using Unigraphics to observe anatomic reproduction with the resurfacing implants.

Results: When placing all resurfacing implants 2 mm from the anatomic neck, the average implant CoR offset from the anatomic CoR was determined to be 1.03 mm ± 0.75 mm. The average implant Humeral Head Thickness (HHT) deviation from the anatomic HHT was determined to be -0.36 mm ± 0.84 mm. There were no significant differences in CoR offset or HHT offset between implant sizes used.

Discussion: Newer generation resurfacing implant designs allow for more anatomic reproduction of the humeral articular surface. Depth of reaming and resurfacing implant height placement are potential pitfalls in humeral head replacement and have been shown to have negative effects on reproducing the CoR and HHT. Using the anatomic neck as a landmark for the depth of reaming has been observed to closely reproduce anatomic HHT and CoR. Further work aims to validate the use of the anatomic neck as a consistent landmark in cadaveric studies and to investigate if these findings are clinically relevant.

Humeral head resurfacing (HHR) is a viable option for patients with end-stage glenohumeral osteoarthritis, rheumatoid arthritis, avascular necrosis, and post-traumatic arthritis.[1] By avoiding the humeral head resection, the HHR is designed to be more bone preserving, and because it does not violate the humeral canal, HHR decreases intraoperative complications, such as peri-prosthetic fractures and excessive blood loss.[2] Other benefits of HHR include its ease of conversion to stemmed arthroplasties, decreased operative time, and its theoretical advantage of more accurately recreating the proximal humeral anatomy.[2] While some authors have found that the HHR, does in fact, better recreate the shoulder anatomy,[3,4] others have found the contrary.[5]

In theory, by avoiding a humeral head resection, the proximal humeral anatomy is preserved, allowing a more accurate recreation and placement of a HHR. Previous authors have described using the intact humeral anatomic neck to maintain the patient's own inclination and version

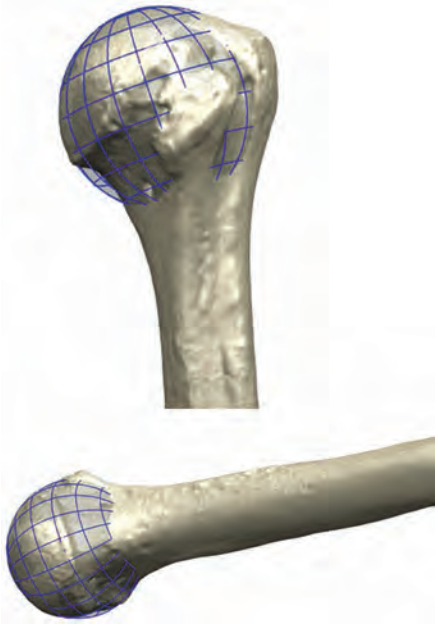

Figure 1 Computer best-fit sphere derived from the humeral head articular surface 3D computer models. The center of the sphere establishes the anatomic CoR. AP view shown on top, axillary view shown below.

Figure 2 Computer image demonstrating the creation of the anatomic neck plane. Multiple points are selected around the humerus along the anatomic neck, and a computer best-fit plane is placed through all points selected to establish the anatomic neck plane.

of the humeral head replacement.[6] While techniques have described placing a HHR parallel with the anatomic neck,[6,7] we are not aware of any description of using the anatomic neck as a reference point for the depth of reaming and the placement of the HHR. This is potentially relevant as one of the more common complications when performing HHR is overstuffing the joint, which can commonly be attributed to inadequate reaming, incomplete implant seating, or to implant design.[3,5]

Iannotti and coworkers validated the use of a sphere on preoperative 3D CT scans and a perfect circle model on postoperative coronal images to asses humeral head anatomy.[8] They used the perfect circle model in a follow-up clinical study showing that surgeons did a better job at recreating the center of rotation (CoR) when using a stemmed arthroplasty compared to when they used HHR. Interestingly, they noted that 89.3% of the time in HHR, there was improper humeral reaming.[9]

The purpose of this study was to use a new resurfacing design along with a perfect sphere model in cadaver CT scans to assess the anatomic neck of the proximal humerus as an accurate landmark for humeral head resurfacing placement, in particular looking at the deviation from the center of rotation and humeral head thickness.

Materials and Methods

Sixty-six cadaveric shoulder CT scans, 34 males (77.0 ± 8.5 years; BMI = 23.8 ± 6.7) and 32 females (76.7 ± 10.5 years; BMI = 21.3 ± 5.8) were reconstructed using Mimics (Materialise NV, Leuven, Belgium) to create 3D models of the humerus. CTs were taken with 0.5 mm slice thickness. Each 3D reconstructed CT model was analyzed in Rapidform (3D Systems) to create a best fit sphere over the humeral head articular surface for measurement of the anatomic radius of curvature, with the center of the sphere establishing the anatomic CoR, as shown in Figure 1. The anatomic neck plane was defined by selecting points circumferentially around the humeral anatomic neck, as

Figure 3 Equinoxe® Resurfacing Humeral Head (Exactech, Inc., Gainesville, FL)

shown in Figure 2, and creating a best fit plane that passed through all points. The anatomic neck angle vector was created for each humerus model by creating a vector normal to the anatomic neck plane, originating from the anatomic CoR. Humeral head resurfacing implant sizes (Equinoxe®, Exactech, Inc.) were selected for each humeral model to most closely match the anatomic radius of curvature (Fig 3). Each resurfacing implant was virtually assembled onto the humeral head 3D reconstructions using Unigraphics (Siemens, Inc.) by constraining the implant coaxially to the anatomic neck angle vector, with a 2 mm gap distance between the anatomic neck plane and the base of the resurfacing implant. The 2 mm gap was selected based on the Equinoxe® system design to seat the HHR implant between 1 mm to 2 mm from the cortical shelf retained by the reamer. If the head is reamed to the depth of the anatomic neck, the result is that the implant will be placed at a 2 mm gap distance from the anatomic neck.

To quantify the deviation from the anatomic CoR, a true AP plane was established by defining a plane passing though the neck angle vector, parallel to the IM axis. The offset distance between the anatomic CoR and the implant CoR was measured with positive x-axis in the medial direction and positive y-axis pointing superior. To evaluate the condition in which the humeral head could be over-reamed, the deviation between the implant humeral head thickness (HHT) from the anatomic head thickness was quantified. The implant HHT was quantified by measuring the distance from the anatomic neck plane to the apex of the resurfacing implant. The anatomic HHT was measured from the anatomic neck plane to the apex of the articular surface. A Student's two-tailed, unpaired t-test was used to identify CoR, and HHT differences between implant sizes where $p < 0.05$ denoted a significant difference.

Results

The mean implant CoR offset from the anatomic for all specimens was determined to be 1.03 mm ± 0.75 mm with the plotted x- and y- offset values for each implant (Fig. 4). The mean CoR offset for female specimens was 0.84 mm ± 0.68 mm, while mean CoR offset in the male group was observed to be higher than females at 1.17 mm ± 0.74 mm.

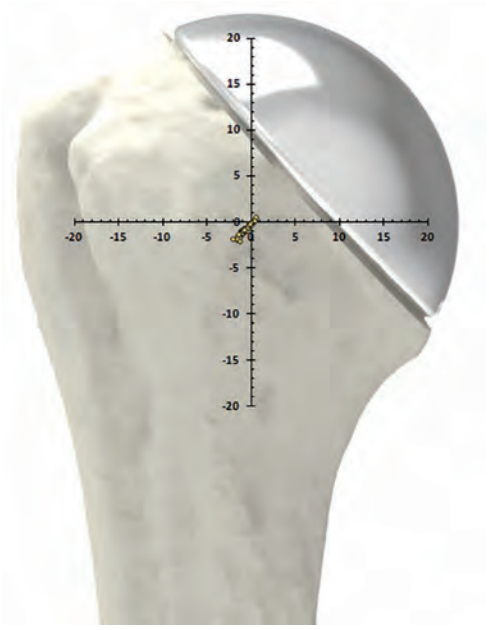

Figure 4 Implant CoR deviation from the anatomic CoR in the x- and y-axes of all specimens. The anatomic CoR is depicted as the plot origin (0,0). The x-axis represents offset in the medial-lateral direction with positive indicating medial. The y-axis represents offset in the superior-inferior direction with positive indicating superior. Both axes are in millimeters.

The average CoR offsets for all specimens were -0.66 mm ± 0.60 mm in the x-axis and -0.62 mm ± 0.60 mm in the y-axis, which indicate an average shift in the implant CoR laterally and inferiorly from the anatomic CoR. As described in Table 1, average total CoR offset was higher for the two largest implant sizes; however, these findings were not statistically significant.

The average implant HHT deviation from the anatomic was determined to be -0.36 mm ± 0.84 mm with the average HHT offsets for each implant size (Table 1). The mean HHT offset for female specimens was determined to be -0.21 mm ± 0.76 mm while the mean HHT offset for males was -0.49 mm ± 0.90 mm. The HHT offset for each analysis is shown in Figure 5, which shows some samples with over-reaming conditions lower than 2 mm below the anatomic

Table 1 The Average Offset of the Implant CoR from the Anatomic CoR and the Average Deviation of the Implant HHT from the Anatomic HHT of the 3D Reconstructed Humerus Model for Each Resurfacing Implant Size Used

Implant Size	CoR Offset* (± Standard Deviation)	HHT Average Deviation (± Standard Deviation)	N
41 mm	0.89 mm ± 0.76 mm	-0.39 mm ± 0.71 mm	7
44 mm	0.89 mm ± 0.73 mm	-0.17 mm ± 1.00 mm	9
47 mm	0.88 mm ± 0.66 mm	-0.31 mm ± 0.72 mm	19
50 mm	1.35 mm ± 1.06 mm	-0.73 mm ± 0.61 mm	8
53 mm	1.15 mm ± 0.72 mm	-0.33 mm ± 0.99 mm	23

HHT. There were no statistically significant differences observed between HHT offsets for each implant size used.

Discussion

The results of this study demonstrate that using the anatomic neck as a landmark for depth of reaming allowed for accurate restoration of the anatomic CoR and HHT with humeral head resurfacing. While it has been described to use the anatomic neck as a guide to determine humeral height positioning, including inclination and version,[6,7] to our knowledge it has not been described to use the anatomic neck as the landmark for determining the appropriate depth of the resurfacing implant position. We believe that this could account, at least in part, for some of the reports of joint overstuffing after a resurfacing procedure[5] and may explain some of the discrepancies found in the literature pertaining to the ability of a HHR to recreate the proximal humeral geometry. The discrepancies may also be implant specific, and our results may also be related to a thinner, more anatomic design. The Equinoxe® resurfacing is a modular implant that utilizes a cannulated system to insert a caged peg into the humeral head allowing for bony through-growth and modular assembly to better reconstruct a patient's anatomy (Fig 3). The humeral prosthesis is only 1.5 mm thick, which is noticeably thinner than the traditional 4 mm thick Copeland HHR device. The instrument system is designed so that the HHR implant sits off the remaining cortical shelf formed from the reamer base. By reaming down to the anatomic neck, the implant is automatically placed at a set distance from the anatomic neck when fully seated.

Mechlenburg and associates concluded, after evaluating the Length of the Gleno-Humeral Offset (LGHO) on standardized radiographs, that the Copeland resurfacing increased the postoperative LGHO, and that this overstuffing of the joint led to a high revision rate (14%).[5] Mansat and colleagues, however, found that HHR did restore the humeral anatomy in their radiographic study,[3] and in a computer model of non-arthritic joints, Hammond and coworkers concluded that the HHR more closely restored the geometric center than stemmed hemiarthroplasty when using an Arthrosurface® implant.[4]

In their clinical study, Alolabi and associates reported that the average deviation of the CoR for HHR was 3.8 mm ± 2.1 mm.[9] When using a computer model to identify and place the humeral component, we found that our average deviation was decreased to 1.03 mm ± 0.75 mm. Obviously, some of this improvement can be explained by the ease of identifying and placing the prosthesis virtually in the computer model, as opposed to identifying the anatomic neck of a deformed humerus intraoperatively and placing a prosthesis based on this. Alolabi and associates stated in their study that finding the anatomic neck in vivo is often difficult and could explain the increased deviation.[9] Whether due to difficulty identifying the anatomic neck or failure to ream to the proper depth, they showed that 89.3% of HHR had improper reaming.[9] We believe that by using the anatomic neck as a landmark for humeral head reaming and subsequent placement of a new, thinner HHR, we are better able to recreate the proximal humeral anatomy decreasing the deviation of the CoR and HHT.

There are several limitations of this study. First, it is a computer model using non-arthritic shoulders. It is much harder to identify the anatomic neck intraoperatively on an arthritic or other deformed shoulder, and future studies will need to evaluate if this technique can be safely and reliably reproduced clinically. Secondly, the use of the anatomic neck as a guide for the reaming depth of the HHR may be design specific, and further studies need to be performed specifically comparing different prosthetic designs placed at the same anatomic location. Although the computer study shows that the HHT can be accurately reproduced, it will need to be determined, clinically, whether or not reaming the humerus to the anatomic neck removes too much subchondral bone to implant a HHR safely. Finally, more clinical studies will need to be performed to evaluate HHR outcomes and whether decreasing the deviation from the CoR improves outcomes.

Conclusions

This computer model demonstrated that using the anatomic neck as a landmark for the depth of reaming with HHR accurately restores the CoR and HHT of the proximal humerus, better than previously reported. Future studies should investigate if this method for HHR placement can be reproduced *in situ* and if these results improve clinical performance.

Optimization of Cemented Glenoid Peg Geometry

A Comparison of Resistance to Axial Distraction

Lisa Becks, M.S., Corey Gaydos, B.S., Nicholas Stroud, M.S., and Christopher P. Roche, M.S., M.B.A.

Abstract

Introduction: Glenoid loosening is one of the most common complications of anatomic total shoulder arthroplasty (aTSA). Numerous glenoid pegged designs exist within the market place; however, little effort has been made to optimize peg geometry, and as a result, there is no consensus regarding the superiority of one design over another. The aim of this study was to determine the impact of peg design on the fixation strength by comparing the force and displacement associated with five different geometries of cemented glenoid components when each is axially displaced from two different densities of polyurethane bone substitute substrates.

Methods: An axial pull-out test was conducted on five different cemented peg geometries in both low- and high-density polyurethane bone-substitute blocks. All substrates were prepared utilizing a drill, which created a 7.3 mm diameter hole to a depth of 26.8 mm. Cemex® brand bone cement was prepared and used to cement all pegs. After cementation of each peg, an electromechanical load frame applied a linear ramp displacement of 10 mm/minute axially to each peg while the polyurethane block was fully constrained. Load and displacement of each peg was sampled at 100 Hz until failure and axial distraction of each peg where the peak pull-out force and associated displacement were recorded. The average load to failure and associated displacement for each peg geometry were compared utilizing the Student's t-test where a p-value < 0.05 determined significance.

Results: Cemented peg design #3 was associated with the greatest axial load to failure (675.3 N ± 18.8 N in low density and 707.3 N ± 11.7 N in high density) for both densities of bone-substitute blocks. Peg designs #5 and #2 were associated with the next highest axial loads to failure in both low and high density blocks. Finally, peg designs #1 and #4 were associated with the lowest axial loads to failure in both low and high density blocks. Only design #3 had a statistically significant difference between peak pull-out forces between the low- and high-density bone substitute blocks, as compared to all other designs.

Conclusions: The results of this study demonstrate that glenoid peg geometry can significantly influence the resistance to axial distraction where the continuous threaded geometry exemplified by peg design #3 demonstrated significantly superior cemented fixation relative to the other peg designs. It can be concluded that overall macrostructure and design of the peg itself plays a key role in pull-out force; however, performance in a clinical setting is required to confirm these biomechanical results.

Glenoid loosening is one of the most common complications of total shoulder arthroplasty and is considered to be the limiting long-term failure mode. The causes of loosening are multi-factorial and include off-center or rim loading, called "rocking horse phenomenon," constrained prosthetic systems that induce too great a torque on the fixation surfaces, poor implantation technique, use in eroded or compromised scapula, and poor cementation technique.[1-3] There are two typical designs of glenoid components, namely keel or peg. Keel designs, as compared to peg designs, require more bone resection and also more cement and have been associated with increased rotation and translation,[4] as well as increased radiolucent lines.[5] Peg glenoids remove less bone and typically require less cement. Numerous glenoid

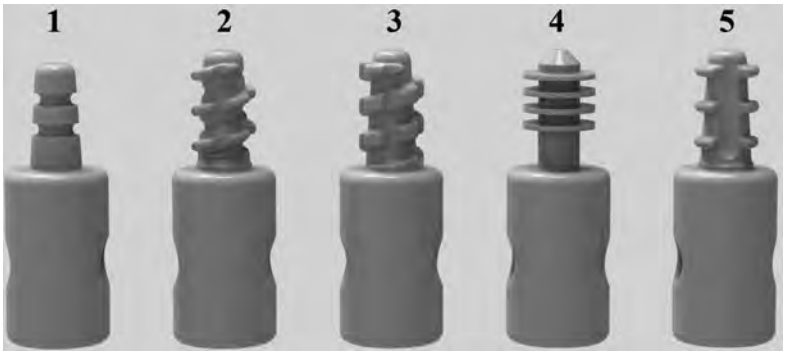

Figure 1 Five different types of peg geometries tested.

pegged designs exist within the market place; however, little effort has been made to optimize peg geometry, and as a result, there is no consensus regarding the superiority of one design over another. The aim of this study is to determine the impact of peg design on the fixation strength by comparing the force and displacement associated with five different geometries of cemented glenoid components when each is axially displaced from two different densities of polyurethane bone substitute substrates.

Materials and Methods

Five unique center peg geometries (Fig. 1) were designed in a 3D computer modeling software (Unigraphics NX, Siemens, Inc.). Each peg design was manufactured from GUR 1050 Ultra High Molecular Weight Polyethylene (UHMWPE) with an equivalent surface finish in order to test cement fixation by axial distraction. All devices were vacuum packaged and gamma-sterilized to a maximum dosage of 37 kGy. Peg designs #1 and #4 were intended to simulate the geometry of FDA-cleared cemented devices with more than 10 years of clinical experience, whereas peg designs #2, #3, and #5 were novel and were intended to maximize cement mantle thickness and uniformity. All pegs were 13.5 mm in length except for design #1, which was only 12 mm long. Similarly, all designs utilized a 7° taper except for design #4, which was cylindrical. Eight samples of each peg geometry were assembled in both low- or high-density polyurethane bone substitute (15 pcf and 30 pcf, respectively) blocks [conforming to ASTM F1839-08(2012) to simulate poor and good quality bone] for a total of 80 tested samples.

Both the low and high density blocks were prepared utilizing a drill creating a 7.3 mm diameter hole to a depth of 26.8 mm. Cemex® brand bone cement (Tecres, Inc., Verona, Italy) was used to cement all pegs. After cementation of each peg to the substrate, an electromechanical load frame applied a linear ramp displacement of 10 mm/minute axially to each peg while the polyurethane block was fully constrained (Fig. 2). To ensure that each test sample was loaded axially, a universal joint was used to link the sample to the test frame. Load and displacement of each peg were sampled at 100 Hz until failure or axial distraction of each peg. The average load to failure and associated displacement for each peg geometry were recorded and compared utilizing the Student's unpaired, two-tailed t-test, where p-value < 0.05 determined significance.

Results

The average axial force required to extract each peg design in both the low and high density polyurethane blocks is described in Figure 3. Numerous differences were noted in the peak pull-out forces between designs and substrate densities (Table 1). Peg design #3 was associated with the greatest axial load to failure (675.3 N ± 18.8 N in low density and 707.3 N ± 11.7 N in high density) for both densities of bone-substitute blocks. Peg designs #5 and #2, respectively, were associated with the next highest axial loads to failure in both low and high density blocks. Finally, peg designs #4 and #1 were associated with the lowest axial loads to failure in both low and high density blocks.

Failure modalities between peg designs were similar

for the high density blocks (in which the peg disassociated from the cement in all cases) but different for the low density blocks, where in some cases the substrate failed prior to the peg disassociating from the cement. Six of the eight tested pegs of peg design #3 failed in the low density block by the substrate fracturing before the peg disassociated from the cement. It should be noted that only four samples of peg design #4 were able to be evaluated in high-density foam due to poor assembly: two of these samples were able to be removed with the force of gravity, and the other two samples had been deformed during assembly such that they could not be attached to the end of the load frame; thus, these samples were excluded from the results. Plastic deformation was observed to some extent on all samples during axial extraction. The average displacement to peak pull-out force for each peg geometry is presented in Figure 4. Differences in mean displacement at peak pull-out force were observed between designs and substrate densities, (Table 2) where design #5 was associated with the lowest displacement.

Discussion

Given the growth of total shoulder arthroplasty over the last decade, the uniformity of belief that the cemented peg glenoid is the gold-standard, and persistent concerns about the complication of aseptic glenoid loosening as the long-

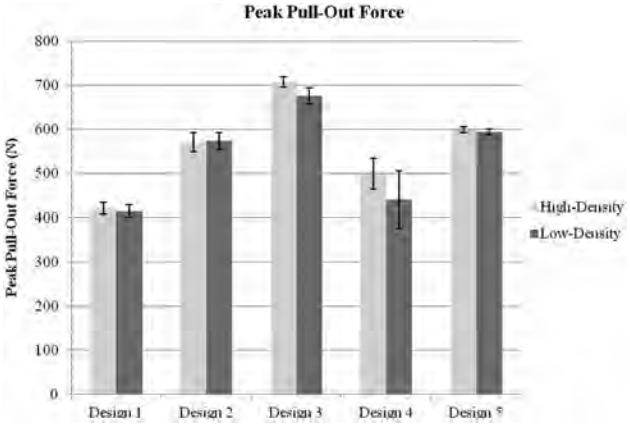

Figure 3 Average peak pull-out force for each test group in low- and high-density bone. The error bars represent one standard deviation.

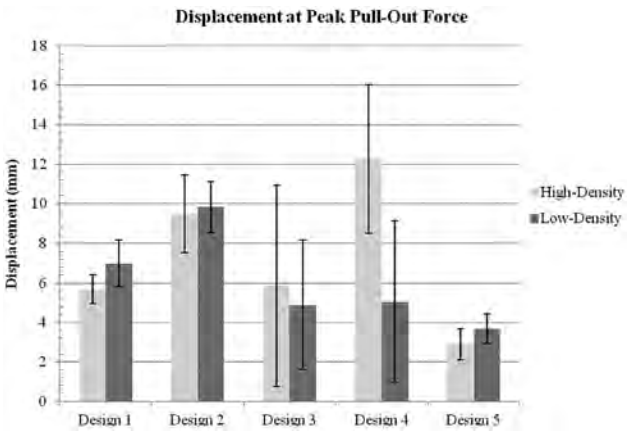

Figure 4 Average load displacement curves at peak pull-out force for each test group in low- and high-density bone. The error bars represent one standard deviation.

term failure mode, it is important that more effort be made to optimize the design of the cemented peg glenoid. Anglin and others have evaluated different design parameters over 15 years ago—but little work has been done since to further refine and optimize the design of the cemented peg glenoid.[6] This current study evaluates the impact of two commercially successful cemented center peg designs, each with over 10 years clinical experience and compares the cemented fixation in both low and high density bone blocks to that of three novel peg geometries that facilitates a more uniform and thicker cement mantle over the length of the peg.

The average peak pull-out results of this study objectively demonstrated that peg geometry #3 provided superior resistance to axial extraction in both low and high density bone-substitute blocks as compared to the other four designs evaluated; however, the displacement at the peak pull-out forces were minimally different between peg designs. The exact reasons for the superior results of design #3 are unclear; however, we suspect that the thicker helical thread form permitted greater flow of the cement around the peg while the larger outer diameter along the length of the peg created greater cement pressurization. Several recent studies in the literature have demonstrated that greater cement pressurization results in a reduction of the incidence of radiolucent lines clinically.[7,8] It may be that a peg geometry, such as utilized in design #3, is able to achieve pressurization without the need for supplemental pressurization instrumentation.

This study has several limitations. We utilized a polyurethane bone-substitute block of two different densities to simulate both good and poor quality bone rather than actual cadaveric bone for reasons of cost and concerns of uniformity in bone quality across all test samples. Improvements to this test could also include the use of a composite substrate to simulate cortical and cancellous bone. Additionally, this test strictly quantified the impact of different peg geometries on axial pull-out strength; we fully recognize that this axial-loading methodology is non-physiological and does not simulate the clinical failure mechanism as described by the rocking horse phenomenon.[6] However, as translational movements of the humeral head on the glenoid component occur during glenohumeral movement, a greater pull-out strength of the fixation pegs can be beneficial for stability of the component.[9]

Future work should evaluate the impact of different cement viscosities and also different thicknesses of cement mantle by the use of different diameters of drills on cemented peg fixation. Additionally, as these results objectively demonstrate that the axial resistance of cemented peg design #3 is superior to the other devices tested, future work should evaluate the combined application of this peg geometry on both central and peripheral pegs. Finally, additional testing to qualify this peg geometry is required to confirm sufficient resistance to the applied torque resulting from eccentric humeral head edge loading by the rocking-horse phenomenon.[6]

Conclusion

The results of this study demonstrate that glenoid peg geometry can significantly influence the resistance to axial distraction, where the continuous threaded geometry exemplified by peg design #3 demonstrated superior cemented fixation relative to the other peg designs tested in this study. It can therefore be concluded that overall macrostructure and design of the peg itself plays a key role in pull-out force of cemented UHMPWE pegs. While the clinical application of this novel peg geometry appears promising based upon the results of this biomechanical study, these laboratory results are not a substitute for clinical performance. Ultimately, long-term clinical follow-up is necessary to demonstrate glenoid design optimization through the reduced incidence of radiolucent lines and aseptic glenoid loosening as a complication.

Optimizing Deltoid Efficiency with Reverse Shoulder Arthroplasty Using a Novel Inset Center of Rotation Glenosphere Design

Christopher P. Roche, M.S., M.B.A., Matthew A. Hamilton, Ph.D., Phong Diep, B.S., Thomas W. Wright, M.D., Pierre-Henri Flurin, M.D., Joseph D. Zuckerman, M.D., and Howard D. Routman, D.O.

Abstract

Introduction: Paul Grammont's hemispherical glenosphere concept medializes the center of rotation (CoR) to the glenoid face to increase deltoid abductor moment arms and improve muscle efficiency. Reducing glenosphere thickness to less than half its spherical radius further medializes the CoR and offers the potential for even greater improvements in efficiency. To that end, this study quantifies deltoid abductor moment arms for six different rTSA prostheses during scapular abduction from 0° to 140°.

Methods: A 3D computer model was developed in Unigraphics to quantify deltoid moment arms during scapular abduction for the normal anatomic shoulder, the 36 mm Grammont Delta III (Depuy, Inc.), 36 mm BIO-RSA® (Tornier, Inc.), the 32 mm RSP® (DJO, Inc.), and the Equinoxe® rTSA (Exactech, Inc.) with three different glenosphere geometries: 38 mm x 21 mm, 46 mm x 25 mm, and the novel 46 mm x 21 mm. Each muscle was simulated as three lines from origin to insertion as the arm was elevated; positional data was exported to Matlab where the abductor moment arms were calculated for the anterior, middle, and posterior deltoid from 0° to 140° humeral abduction in the scapular plane using a 1.8:1 scapular rhythm.

Results: The 46 mm x 21 mm glenosphere had the largest average abductor moment arms and also the largest efficiency for all three heads of the deltoid, having a 4.8% to 40.7% increase in the average deltoid efficiency relative to all other designs tested. The glenosphere design with the next most efficient deltoid was the 36 mm Delta III, which had the next most medialized CoR. The two least efficient designs were the BIO-RSA® and the DJO RSP®, which had the most lateral CoR.

Discussion: These results provide new biomechanical insights on the impact of glenosphere geometry on deltoid abductor moment arms and demonstrate that subtle changes in rTSA prosthesis design can result in dramatic improvements. Increasing glenosphere diameter while also decreasing thickness to be less than half its spherical radius may minimize the muscle forces required to perform activities of daily living. Clinical follow-up is necessary to demonstrate a reduction in complications related to joint over-loading and also demonstrate greater increases in range of motion for patients with weak musculature.

Much of the recent clinical and commercial success associated with reverse total shoulder arthroplasty (rTSA) can be attributed to Paul Grammont's innovations in shoulder prosthesis design. In 1991, Grammont first recommended a glenosphere geometry in which the thickness was one-half its diameter to position the center of rotation (CoR) directly on the glenoid face in order to reduce torque on the glenoid fixation interface while also increasing the deltoid abductor moment arms in order to improve deltoid efficiency.[1] This hemispherical glenosphere concept has been the geometric predicate for nearly every rTSA prosthesis released in the global marketplace since that time. The primary design variation in glenosphere geometry has been to increase the thickness relative to the spherical radius in order to lateralize the CoR and also lateralize the

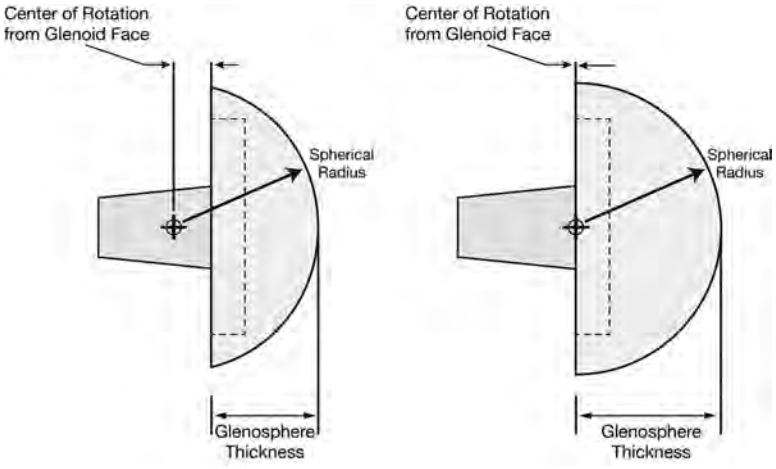

Figure 1 Medializing the CoR with a glenosphere prosthesis design in which the thickness is less than its spherical radius (left image) to further increase the deltoid abductor moment arm lengths relative to the Grammont glenosphere design having a thickness equal to its spherical radius to place the CoR on the face of the glenoid (right image).

humerus to reduce the incidence of humeral liner impingement on the scapula and reduce the scapular notching rate.[2-4]

To our knowledge, no one has ever conceived of a glenosphere design whose thickness is less than its spherical radius; theoretically, such a glenosphere geometry would have a more medialized CoR, which would further increase the deltoid abductor moment arms and further improve deltoid efficiency (Fig. 1). Exactech has recently developed and gained 510(k) clearance for such a device.[5] The Equinoxe® 46 mm x 21 mm glenosphere is 4 mm thinner than the standard Equinoxe® 46 mm x 25 mm glenosphere to medially inset the CoR within the glenoid bone and increase the deltoid abductor moment arms to reduce the force necessary to elevate the arm (Fig. 2). Additionally, this thinner glenosphere geometry effectively decreases the anterior-posterior width of the device to make it 2 mm smaller and permit a better anatomic fit and improve the ease of insertion.

A minimum glenosphere thickness is necessary to sustain sufficient muscle tensioning—as rTSA designs have been previously demonstrated to shorten the rotator cuff[6-9]; for this reason, a larger diameter glenosphere of 46 mm was utilized in this design concept to ensure at least 21 mm of glenoid sided humeral lateralization was achieved. Additionally, a maximum glenosphere thickness to permit sufficient motion prior to boney impingement may exist[2-4]; for this reason, we selected a 46 mm diameter design instead of a significantly larger concept, like a 60 mm x 25 mm glenosphere, which would result in even greater medialization of the CoR but likely have a reduced range of motion in the clinical setting. The purpose of this computer study is to quantify the impact of modifying glenosphere geometry as described on the deltoid abductor moment arms during abduction in the scapular plane from 0° to 140°.

Figure 2 Equinoxe® 46 mm x 21 mm inset CoR glenosphere (Exactech, Inc.; Gainesville, FL).

Methods

A 3D computer model was developed in Unigraphics (Siemens, Inc.) to quantify muscle moment arms during various simulated shoulder motions. This muscle model has been utilized prior to compare the impact of different prosthesis designs, glenoid bone deformities, humeral implantation techniques, and glenoid implantation techniques on muscle lengths, deltoid wrapping, and muscle moment arms.[6-14] In this study, we quantified the abductor moment arms of the anterior, middle, and posterior heads of the deltoid during scapular abduction for the normal anatomic shoulder, the 36 mm Grammont Delta III (Depuy, Inc.), 36 mm Grammont BIO-RSA® (Tornier, Inc.), the 32 mm RSP® (DJO, Inc.), and the Equinoxe® rTSA (Exactech, Inc.) with three different glenosphere geometries: 38 mm x 21 mm, 46 mm x 25 mm, and the aforementioned novel 46 mm x 21 mm. Each of these implants were geometrically modeled and implanted in a 3D digitized scapula and humerus (Pacific Research, Inc.) so that each glenoid baseplate aligns with the inferior glenoid rim as the humeral component was oriented in 20° retroversion. The computer simulated each muscle as three lines from origin to insertion as the arm was elevated; positional data was exported to Matlab® (Mathworks, Inc.) where the abductor moment arms were calculated for the anterior, middle, and

posterior deltoid from 0° to 140° humeral abduction in the scapular plane using a 1.8:1 scapular rhythm.

Results

The abductor moment arms for the anterior, middle, and posterior heads of the deltoid for each glenosphere geometry and the normal anatomic shoulder during scapular abduction from 0° to 140° are presented in Figures 3, 4, and 5, respectively. The average increase in the abductor muscle moment arms relative to the normal anatomic shoulder for each glenosphere geometry is termed deltoid efficiency and is presented in Table 1. As described in these Figures and Table 1, the 46 x 21 mm glenosphere was associated with the largest average abductor moment arms and also the largest efficiency for all three heads of the deltoid with the greatest increases at low to mid ranges of elevation. Specifically, the 46 x 21 mm glenosphere was associated with a 4.8% to 40.7% increase in the average deltoid efficiency relative to all of the other glenosphere designs tested. The glenosphere design with the next most efficient deltoid was the 36 mm Grammont Delta III, which had the next most medialized CoR. The use of 10 mm of bone graft behind the baseplate with the BIO-RSA® technique made this device significantly less efficient, resulting in a 29.4% decrease in anterior deltoid efficiency, 30.2% decrease in middle deltoid efficiency, and a 28.7% decrease in posterior deltoid efficiency. As expected, the 32 mm DJO RSP® device with the most lateral CoR position was the least efficient of all rTSA designs tested.

Discussion

The results of this study demonstrate that a wide range of design variability exists in the glenoid component with rTSA and

Table 1 Average Increase in Deltoid Abductor Moment Arms Relative to the Normal Anatomic Shoulder during Scapular Abduction from 0° to 140°

	Average Deltoid Efficiency			% Decrease in Abductor Moment Arm Efficiency Relative to the 46 mm Inset CoR Glenosphere		
	Ant Deltoid	Middle Deltoid	Post Deltoid	Ant Deltoid	Middle Deltoid	Post Deltoid
36 mm Grammont Delta III	124.2%	122.1%	121.7%	10.2%	4.8%	10.5%
36 mm Grammont BIO-RSA®	94.8%	91.9%	93.1%	39.7%	35.1%	39.2%
32 mm DJO RSP®	93.7%	89.1%	91.6%	40.7%	37.8%	40.7%
38 mm Equinoxe®	116.7%	110.8%	114.8%	16.7%	16.2%	17.5%
46 mm Equinoxe®	119.9%	112.7%	117.3%	14.5%	14.3%	15.0%
46 mm Inset CoR Equinoxe®	134.4%	126.9%	132.3%	NA	NA	NA

that the abductor moment arms of the deltoid can be increased by subtle changes in glenosphere geometry, where the novel 46 mm x 21 mm inset CoR glenosphere was associated with a 4.8% to 40.7% increase in deltoid efficiency relative to the other glenosphere designs having either similar diameters or thicknesses. For example, the 38 mm x 21 mm and 46 mm x 25 mm Equinoxe® glenospheres, being nearly equivalent sections of spheres (55.3% and 54.3%, respectively) had nearly equivalent CoR and as such were associated with the most similar deltoid abductor moment arms. Conversely, the 46 mm x 21 mm glenosphere, being a smaller section of a sphere (45.7%), had a CoR that was 4 mm more medial than the other Equinoxe® glenospheres and as a result had a 14.3% to 17.5% increase in average deltoid efficiency.

Larger abductor moment arms increase the efficiency of the deltoid and by definition proportionally decrease the force necessary by each muscle to elevate the arm.[15-19] Previous work has demonstrated that lateralizing the CoR by increasing glenosphere thickness independent of its diameter decreases the deltoid abductor moment arms and reduces deltoid efficiency.[9,14,20] This computer analysis builds upon that work by demonstrating that deltoid abductor moment arms can be further increased with rTSA by decreasing glenosphere thickness to less than its spherical radius. The results of this sudy demonstrate that the two designs which lateralize the position of the CoR the most (32 mm DJO RSP® and 36 mm BIO-RSA®) were also associated with the lowest deltoid abductor moment arms and lowest deltoid efficiency, confirming that currently marketed designs are not optimized.

Future design advancements, such as this proposed glenosphere concept, offer the potential to improve function with next generation reverse shoulder prostheses and may also offer the potential for more refined applications. For example, a patient with a boney deficient glenoid who is at risk of glenoid loosening or a patient with a thin acromion or scapula who is at risk for a stress fracture may benefit from the use of a more efficient glenosphere design, which would theoretically reduce the muscle forces necessary for arm mobility and in turn decrease the overall joint reaction forces. Additional increases in range of motion may also be achieved for patients with weak musculature, though clinical follow-up with this device is necessary to confirm such theoretical benefits.

This study has some limitations. Interpretations of these findings are limited by its computer evaluation of deltoid abductor moment arms in only one digitized anatomy during only one type of motion. Future work should evaluate the impact of this novel glenosphere geometry in multiple different anatomies during different motions for multiple different muscles. The impact of different implantation techniques and positions should also be considered.

Conclusions

This computer analysis provides new biomechanical insights on the impact of glenosphere geometry on deltoid abductor moment arms with rTSA and demonstrates that subtle changes in prosthesis design can result in dramatic biomechanical improvements. This novel design concept of increasing glenosphere diameter while also decreasing thickness to be less than half its spherical radius was associated with improvements in efficiency as large as 40.7% relative to the other marketed designs and may be useful to orthopaedic surgeons, designers, and manufacturers to develop future generations of prostheses that minimize the forces required by the deltoid to elevate the arm; thereby, reducing the overall joint reaction force. Clinical follow-up using such next generation prosthesis ideas may demonstrate a reduction in complications related to joint over-loading, such as aseptic glenoid loosening and scapular stress fractures, and may also demonstrate greater increases in range of motion for patients with weak musculature.

Improving Distal Fixation with Total Shoulder Arthroplasty in Cases of Severe Humeral Bone Loss

Amanda Jacobson, B.S., Nick Stroud, M.S., and Christopher P. Roche, M.S., M.B.A.

Abstract

The usage of and indications for total shoulder arthroplasty have grown in recent years. Certain aspects of these arthroplasty procedures can be very complex, especially in revision and fracture cases, often leading to proximal humerus bone loss. For cases with significant bone loss, there is a need for improved devices with additional options to treat a wider range of deformities while also mitigating existing complications and rates, such as poor distal fixation, inadequate soft tissue reattachment options, and joint instability. To that end, a fatigue and torsional test was conducted on two different devices to assess the ability of each to survive an extreme fatigue and torsional load when assembled in worst-case configurations. Evaluation of the Equinoxe® humeral reconstruction prosthesis demonstrated superior fixation in both the fatigue loading scenario and also the torsional loading scenario as compared to the 8 mm x 215 mm cemented humeral long stem, where each had only 80 mm of cemented fixation. The results of the fatigue test demonstrated that despite the humeral reconstruction prosthesis being subjected to a 960 N force and 45 Nm bending moment (which was significantly more challenging than the 576 N force and 24.2 Nm bending moment subjected to the cemented humeral long stem), the humeral reconstruction prosthesis completed 1 M cycles without fracture or failure. Additionally, the Equinoxe® humeral reconstruction prosthesis was associated with a significantly greater torsional resistance in both the torque to initial slip (29.4 Nm versus 8.2 Nm; $p = 0.0002$) and also the maximum torque to failure (44.3 Nm versus 12.1 Nm; $p < 0.0001$). These significant improvements in fixation are at least partially attributed to the application of a novel distal fixation ring, which is press fit around the diaphysis of the humerus to supplement the cemented fixation of the distal stem. These fatigue and torsional test results paired with several novel features offer the potential for the Equinoxe® humeral reconstruction prosthesis to be an improved treatment option for patients with proximal humeral bone loss, though clinical follow-up is necessary to confirm these positive biomechanical results.

Usage of total shoulder arthroplasty, both anatomic (aTSA) and reverse (rTSA), has increased significantly over the past decade. Indications for shoulder arthroplasty have expanded, as have the number of surgeons performing these operations. Consequently, for a multitude of reasons that include patient selection, pathoanatomy, surgical technique, and experience with shoulder arthroplasty, a concomitant increase in humeral failures are expected. Instances of humeral failure are accompanied by proximal humeral bone loss that results from the effects of aseptic prosthetic loosening, the destructive nature of humeral prosthetic explantation, or occasionally both. Loss of proximal humeral bone has implications on function and stability, which can potentially compromise stem fixation, musculotendinous insertions and also impair the stabilizing effects of deltoid wrapping. Along with the increased usage of rTSA for revisions, proximal humeral trauma and its sequelae and tumor resections, clearly, complex reconstruction of humerus will become more prevalent in the coming years.[1]

While revision shoulder arthroplasty systems are currently available,[2-11] none are platform humeral stems that are FDA cleared for use in hemiarthroplasty, aTSA, and rTSA with proximal humeral bone loss. Features shared by the existing implants include limited distal stem rotational stability and a propensity for prosthetic joint instability in part, from failure to take advantage of opportunities for soft

Figure 1 Equinoxe® humeral reconstruction prosthesis (Exactech, Inc.; Gainesville, FL).

tissue tension and its attachment to the bone or prosthesis.[6-11] Aiming to improve both stability and fixation in such difficult revision cases, Exactech has developed the Equinoxe® humeral reconstruction prosthesis (Fig. 1). This unique device has gained FDA clearance for shoulder reconstructions that incorporate hemiarthroplasty, aTSA, and rTSA in the presence of significant proximal humeral bone loss.[12] This highly modular device is composed of solution heated-treated and aged Ti-6Al-4V and consists of a cemented distal stem (6 mm to 13 mm), a press-fit distal fixation collars (17 mm to 33 mm), middle segments (25 mm to 75 mm), and an electro-polished proximal body (four sizes, in two different heights). In combination, this size offering permits humeral reconstructions from 50 mm to 222.5 mm from the top of the humeral head in 12.5 mm increments. These segments are secured together by taper impaction and are locked using a screw which spans the entire distance from the distal stem to the proximal body. Additionally, the Equinoxe® humeral reconstruction prosthesis provides four different sizes of proximal bodies to lateralize the deltoid and encourages additional deltoid wrapping to improve stability. These proximal bodies include numerous recessed plasma-coated regions for soft tissue attachment that are surrounded by suture grooves to avoid suture abrasion (Figs. 2 and 3). The purpose of this study was to analyze and compare the distal fixation that results when the novel Equinoxe® humeral reconstruction prosthesis and the existing Equinoxe® cemented humeral long stem are tested in a simulated humeral reconstruction using two different extreme loading scenarios (fatigue and torsion).

Methodology

This biomechanical study consists of two different tests. The first test quantifies the fatigue resistance of the Equinoxe® humeral reconstruction prosthesis and the Equinoxe® cemented humeral long stem when oriented and assembled in worst case configurations and utilized in a mid-humeral resection with a minimum 80 mm cemented stem length. The second test quantifies the resistance of each aforementioned cemented humeral stem to a static torsional load.

For the fatigue test, the humeral reconstruction prosthesis was tested with a 6 mm x 80 mm distal stem using two 75 mm middle segments, which is the longest recommended configuration with the smallest humeral stem and therefore represents a worst-case configuration because it creates the largest moment under loading. The Equinoxe cemented humeral long stem tested was 8 mm x 215 mm, which was larger than the 6 mm diameter of the humeral reconstruction prosthesis. The loading parameters between the two stems were different with the cemented humeral long stem being tested under a significantly less extreme loading orientation because previous feasibility testing demonstrated immediate failure when tested identically. These differences are outlined in Table 1. The cemented humeral long stem was tested at 1.5 Hz with a peak force of 576 N until 1 M cycles or failure. Conversely, the humeral reconstruction prosthesis was

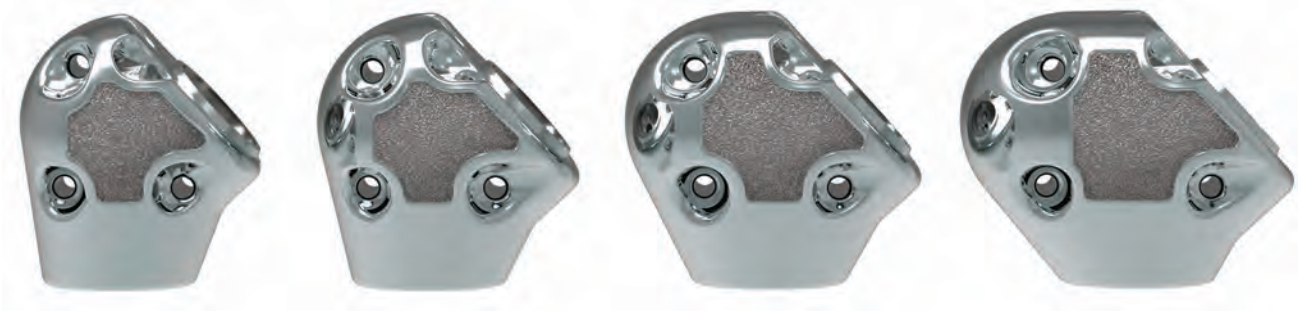

Figure 2 Four sizes of proximal body options to lateralize the proximal humerus to improve soft tissue tensioning and increase deltoid wrapping.

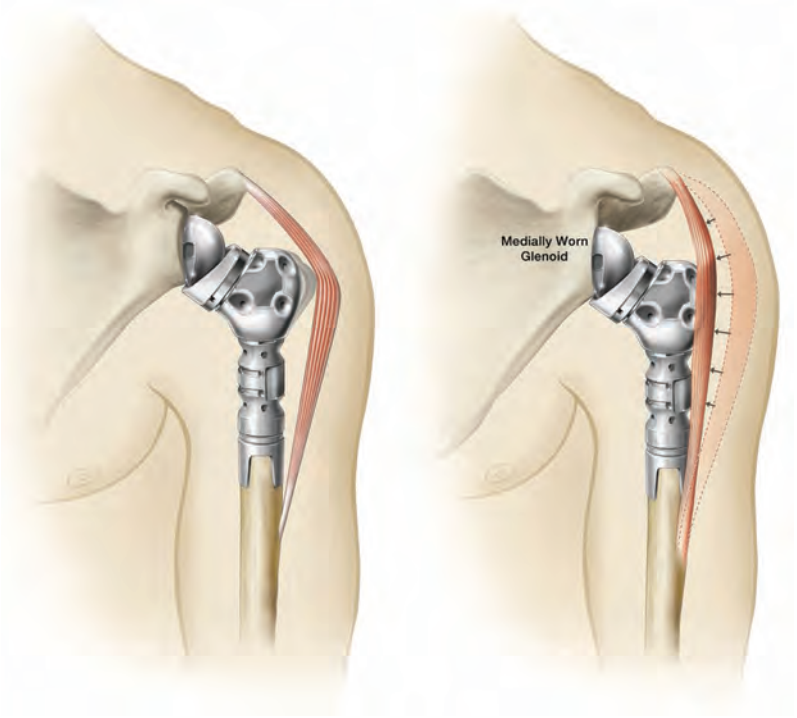

Figure 3 Use of proximal humeral bodies to improve deltoid wrapping in normal (left) and medially worn (right) glenoid.

tested at 1 Hz with a peak force of 960 N until 1 M cycles or failure. Five humeral reconstruction prostheses and three of the cemented humeral long stems were tested.

For the torsional test, the rotational stability of the Equinoxe® humeral reconstruction prosthesis (6 mm x 80 mm distal stem) and the Equinoxe® cemented humeral long stem (8 mm x 215 mm) were quantified under identical loading conditions. Five of each device were tested. Additionally, all tested humeral stems had an equivalent length of 80 mm cemented distally into the fourth generation composite, dual density humerus (Pacific Research, Inc., Vashon, WA) with a 1.63 g/cm^3 "cortical" shell and a 0.27 g/cm^3 "cancellous" interior structure. The assemblies were loaded at a rate of 10 N/sec until the compressive axial load reached 100 N. The axial force was then maintained while a 6º/minute rotational displacement was applied until specimen failure. Figure 4 depicts the test set-up of both the humeral reconstruction prosthesis and the cemented humeral long stem.

Table 1 Different Fatigue Loading Conditions for the Cemented Humeral Long Stem and Humeral Reconstruction Prosthesis

	Cemented Humeral Long Stem	Humeral Reconstruction Prosthesis
Abduction	17º ± 1º	10º ± 1º
Flexion	7.5º ±1º	10º ± 1º
Internal Rotation	0º	45º ± 1º
Peak Force	~576 N	~960 N
Moment	24.2 Nm	45 Nm
Frequency	1.5 Hz	1 Hz

Results

The results of the fatigue test are presented in Table 2. As described, all three cemented humeral long stems failed at

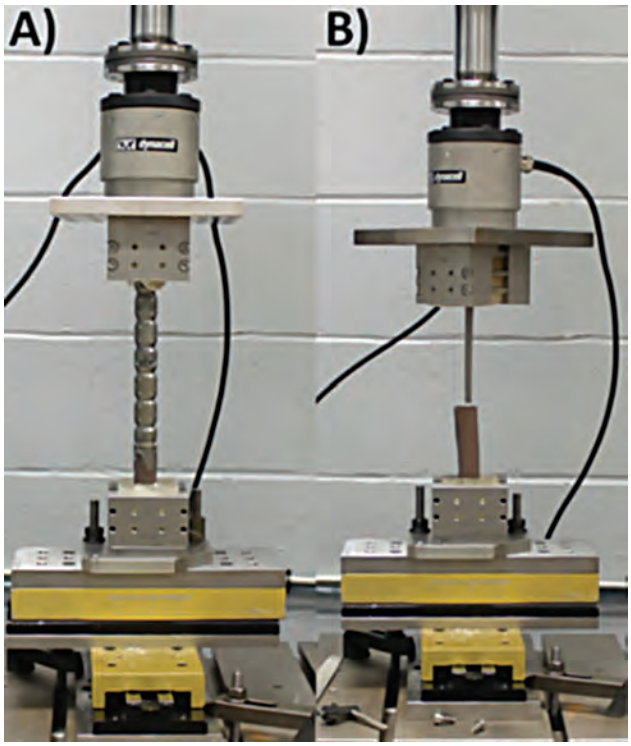

Figure 4 Torsion testing set-up. **A**, Humeral reconstruction prosthesis and **B**, cemented humeral long stem.

an average of 218,914 ± 167,338 cycles, whereas all five humeral reconstruction prostheses completed 1 M cycles without failure at nearly twice the applied torque. All three cemented humeral long stems were tested in composite humeri; whereas, two of the humeral reconstruction prostheses were tested in composite humeri and three were tested in hollow aluminum pipe. This difference in substrate was due to the more extreme forces and torques applied to the humeral reconstruction prosthesis compared to the cemented humeral long stem. It was assumed that the composite humerus specimens would indicate the quality of fixation between implant and irregularly shaped humerus, as well as stress the 6 mm diameter humeral stem. In contrast, the rigid fixation provided by the aluminum cylinders was assumed to provide higher stresses at the distal fixation ring given the increased stiffness at the implant-aluminum boundary. Regardless of the substrate, all five of the reconstruction prostheses survived loading without fracture or failure.

The results of the torsional test are presented in Table 3. As described, the average applied torque to initiate slipping of the cemented humeral long stem was 8.2 Nm versus 29.4 Nm for the humeral reconstruction prosthesis. Additionally, the average max torque to failure of the cemented humeral long stem was 12.1 Nm versus 44.3 Nm for the humeral reconstruction prosthesis. For all samples, the humeral reconstruction prosthesis withstood higher torques than the cemented humeral long stem, with an average torque difference of 21.1 Nm and 32.1 Nm for slipping and max torque, respectively.

Discussion

These results demonstrate both superior fatigue and torsional strength of the Equinoxe® humeral reconstruction prosthesis relative to the 8 mm x 215 mm cemented humeral long stem, where each had only 80 mm of cemented stem fixation. Despite the Equinoxe® humeral reconstruction prosthesis being subjected to a 960 N force and 45 Nm bending moment in the fatigue test (which was significantly more challenging than the 576 N force and 24.2 Nm bending moment subjected to the Equinoxe cemented humeral long stem), the humeral reconstruction stem reached 1 M cycles without fracture or failure despite this 56.3% higher peak forces. Additionally, the Equinoxe® humeral reconstruction prosthesis was associated with a significantly greater torsional resistance in

toque to initial slip (29.4 Nm versus 8.2 Nm; p = 0.0002) and also in maximum torque to failure (44.3 Nm versus 12.1 Nm; p < 0.0001)

This study is limited by the use of a relatively small sample size in each test, the different loading conditions in the fatigue test, and also by the use of a composite humeri substrate instead of cadaveric bone. When comparing these torque-to-failure values in this study to that of cadaveric humeri in a study by Schopfer[13] (humeri of an average age of 75 years), the reported peak torque to failure was 53 Nm ± 17 Nm. While this torque to failure of cadaveric bone was greater than either value in this study, it is worth noting that the Equinoxe® humeral reconstruction prosthesis was much closer to the reported torsional strength of the cadaveric humeral bone—and it may not be reasonable to expect a reconstructed humeral arthroplasty to approach the torsional strength of the native bone. The significant increases in torsional strength relative to the cemented humeral long stem is likely attributed to the distal fixation ring component. Future testing should isolate the additive impact of the distal collars on rotational stability, particularly when utilized in different bone morphologies or different density of bone. However, it is clear based on these results that the diaphyseal fit of this component provides a significant advantage compared to cemented stems without a similar supplemental means for distal fixation. Finally, as all tested Equinoxe® humeral reconstruction prostheses completed 1 M cycles in the fatigue test, the test was stopped for each component prior to failure. Therefore, future work should continue to test this device using the same methodology until failure in order to better identify the fatigue limits and failure modalities.

Conclusions

These fatigue and torsional study results demonstrate that the Equinoxe® humeral reconstruction prosthesis offers the potential for improved strength and stability when used with severe proximal bone loss, relative to the cemented humeral long stem. Patients with severe humeral bone loss may benefit from such a device with improved distal fixation and additional options for joint stability and soft tissue attachment. Clinical follow-up is necessary to confirm these positive biomechanical results.

Evaluation of Preoperative Implant Placement in Total Shoulder Arthroplasty

Matthew A. Hamilton, Ph.D., Sandrine Polakovic, M.S., Paul Saadi, M.D., Richard B. Jones, M.D., Ira M. Parsons, M.D., and Emilie V. Cheung, M.D.

Abstract

Introduction: New technology to assist with glenoid placement in shoulder arthroplasty has evolved to include preoperative planning tools and intraoperative guides. These tools provide surgeons with a more complete understanding of glenoid anatomy prior to surgery. However, there have been no studies identifying the information that most influences surgical decision making. Further, there have been few studies that quantify intraoperative identification of scapular landmarks required to execute a preoperative plan. The purpose of this study is to examine the variables that are considered when making a preoperative plan in shoulder arthroplasty.

Methods: The first part of this study was a cadaveric lab in which three surgeons identified the neutral axis in surgical simulation. The second part of the study utilized a preliminary software tool in which surgeons were able to place glenoid implants in a set of CT reconstructions utilizing standard pegged glenoid components. In the third part of the study, surgeons utilized a novel planning software that included the ability to view the 3D reconstructed glenoid in all planes simultaneously and place either standard or augmented glenoid implants. The results of these three studies were compared.

Results: The center of the glenoid identified in the cadaver lab was 1.69 mm ± 1.58 mm anterior and 1.99 mm ± 2.49 mm superior to center. The identified neutral axis was tilted 14.2° ± 9.2° superior to the Friedman axis with 11.8° ± 7.9° of retroversion relative to that axis. Using the novel preoperative planning tool, the surgeons placed implants less than 0.5 mm from the center of the glenoid (AP = -0.07 mm ± 0.42 mm, SI = 0.44 mm ± 0.82 mm) with an average retroversion of less than 1° (-0.96° ± 3.04°).

Conclusion: There was a discernible difference between the neutral axis identified in the cadaveric simulation (average of 14.2° superior and 11.8° retroverted) and the implant orientation planned using preoperative software (average of 3.26° superior and 0.96° retroverted). Based on the variability of position and orientation seen cadaverically, it is concluded that additional intraoperative guidance is needed alongside a preoperative plan in order to execute ideal placement of the glenoid component.

As advanced imaging modalities in the shoulder continue to expand, the surgeon has more powerful tools to optimize surgical precision and techniques. In total shoulder arthroplasty, computerized tomography (CT) scans provide valuable insight into patient bony anatomy of the glenoid that cannot be fully appreciated during actual surgery.[1] Simply visualizing the 3D form of the bone has been credited for improving a surgeon's preparation preoperatively. Recently, tools have emerged that expand on a simple 3D representation and provide complete preoperative planning of the scapula, including implant options. Planning a case preoperatively allows the surgeon to anticipate clinical challenges (e.g., perforation, version correction, bony anomalies). Multiple studies have compared a surgeon's plan to the placement achieved using instrumentation or patient specific guides.[2,3] The data show that with traditional instrumentation, a surgeon can generally place an implant within 15° of neutral in terms of retroversion and inclination, but with higher degrees of preoperative deformity, the operative placement is less predictable. described a method for identifying the "glenoid vault" of the scapula in order to provide guidance on the proper implant alignment.[4,5] By fitting the idealized glenoid vault shape to the deformed scapular bone, the software utilized in their study made a recommendation on the proper position and orientation of the glenoid component using the assumption that the center of the glenoid vault was the ideal placement for the center of the glenoid implant.

However, the subtleties behind preoperative and intraoperative surgical decision making have yet to be quantified. The goal of this study is to document the variables considered when implanting a glenoid prosthesis. The center of the glenoid prosthesis was quantified relative to Friedman's line during three scenarios: 1. utilizing simulated surgery in a cadaver lab, 2. utilizing "virtual surgery" in which glenoid components were placed within 3D CT scapulae with standard non-augmented components, and 3. utilizing "virtual surgery" in which glenoid components were placed within 3D imaging of the scapula using augmented glenoid components.

Materials and Methods

Simulated Surgery Using Cadavers

Nine cadaveric shoulders were used in the simulated surgery portion of the study. Three surgeons (EC, PS, RJ) exposed the shoulder joint utilizing a deltopectoral approach in each specimen. The humerus was prepared by making a cut along the anatomic neck of the humerus as determined by the surgeon. The ExactechGPS® navigation system (Gainesville, FL) was used to capture points on the scapular bone for use in registration with the 3D reconstruction of the bone. After capture of the scapular points, the system was used to track the position of the scapula relative to the probe for each cadaver. The surgeons were asked to identify the center of the glenoid using a tracked probe tip (Fig. 1). They were then asked to orient a shaft along the neutral axis of the scapula for reaming. The navigation system simply collected data throughout this process. It provided no guidance on alignment during assessment of the glenoid. The surgeons were only allowed to select the data one time per specimen and then had to move to the next. This rotation was repeated until each surgeon collected data on the specimen three times to minimize the influence of repeated data collection.

Glenoid Placement Using Preliminary Software

The nine cadaveric specimens used in the first portion of this study were CT scanned prior to the simulated surgeries. CT scans were reconstructed using Mimics® Innovation Suite v16.0 (Leuven, Belgium). Each image or slice of the scan was manually segmented using a threshold technique to discern the cortical bone geometry of the slice. The slices were merged to create the 3D representation of each scapula. The 3D reconstructions were imported into a 3D modeling software (Unigraphics NX 7.5, Siemens Inc., Plano, TX) along with a pegged glenoid component. Two orthopedic surgeons (EC and PS) used the software to place standard glenoid implants onto the scapulae based on their preferred positioning. No scapular coordinate system was defined in this software and parts were placed solely on the subjective determination of the "best fit." After glenoid placement, a coordinate system was built for the scapula within Geomagic Design™ X based on the Friedman axis. The coordinate system was constructed by identifying the center of the trigonum on the medial border of the scapula, the distal-most point, and the geometric center of the glenoid.

The version and inclination of the reconstructed scapulae were measured. The position and orientation of each glenoid component were compared to the "neutral" axis of the scapula as defined by the Friedman axis, and the "neutral" axis that was identified intraoperatively.[6]

Glenoid Placement Using Novel Preoperative Planning Software

An additional 10 previously obtained unrelated CT scans were reconstructed using custom-written CT segmentation software (Blue Ortho, Grenoble, France) following a similar threshold-based process. These reconstructions along with the CT images were imported into custom-written preoperative planning software (Blue Ortho, Grenoble, France) in which the surgeons could perform "virtual surgery." Both traditional glenoid implants and augmented implants were available for selection. The software also included the ability to visualize the CT slices and the identified axes of the scapula. The position and orientation of the implant followed the Friedman axis. Each surgeon positioned their selected implant in the preferred position and orientation. These positions were measured relative to the previously defined coordinate system of the scapula. Differences between "ideal" placement of the glenoid and the neutral position were then calculated.

The results of glenoid placement using the preliminary software and the novel software were compared using a Student's t-test. An unpaired, two-tailed t-test was chosen since the two datasets are independent of one another.

Results

Simulated Surgery Using Cadavers

The nine cadaveric specimens were assessed in a simulated surgery. The point identified as the center of the glenoid in the cadaver lab was anterior and superior to the geometric center identified using the 3D reconstruction of the bone. The average offset was 1.69 mm ± 1.58 mm anterior and 1.99 mm ± 2.49 mm superior to the center (Fig. 2). The identified neutral axis was generally tilted superior to the Friedman axis and in a greater degree of retroversion. The average retroversion was 11.8° ± 7.9°, and the average inclination was 14.2° ± 9.2° of superior tilt. The "neutral" axis identified cadaverically correlated with the retroversion of the bone.

Glenoid Placement Using Preliminary Software

The glenoid placement using the preliminary software tool was closer to the center than what was identified in the cadaver lab. The average position for the virtually placed

Figure 1 The probe used in this study consists of a handle with active trackers for positioning and a spherical tip used to probe the surface. The axis of this probe was used to identify the neutral axis in the cadaveric assessment.

glenoids was 0.41 mm ± 1.09 mm anterior to the glenoid center and 0.69 mm ± 1.65 mm superior to the glenoid center. The difference between the glenoid component and the neutral axis (8.88° ± 4.69° retroverted and 4.35° ± 6.04° inferior tilt) was less than the difference between the neutral axis identified cadaverically and the actual neutral axis. The key factors used to determine the placement of the implant were bony coverage, fixation pegs within the body of the scapula, version correction, and subchondral bone preservation. These considerations were cited as reasons why the implants were not placed in the neutral position.

Glenoid Placement Using Novel Preoperative Planning Software

The glenoid placement using the novel custom-written planning tool on an additional 10 CT scans demonstrated an implant placement closer to the center of the glenoid face than simply using the 3D reconstructions of the bone with no coordinate system defined (0.07 mm ± 0.42 mm posterior to the center and 0.44 mm ± 0.82 mm superior to the center).

The orientation of the glenoid using the novel software tool was corrected closer to the neutral axis than what was found in the initial placement study using the preliminary software tool (3.26° ± 4.25° superiorly tilted and 0.96° ± 3.04° of retroversion). A Student's t-test (two-tailed, unpaired) was performed on the two datasets (Table 1) and revealed that the implant retroversion was the only variable to reach statistical significance. However, the preliminary software tool only allowed standard pegged glenoid options and did not include the ability to select augmented implants. Subchondral bone preservation was noted as a consideration when placing the implants, and many implants were placed in retroversion in order to balance version correction and bone preservation. The addition of augmented glenoid

Neutral axis retroversion identified on cadavers (right-bottom, red), measured inclination using 3D representation (right-bottom, blue).

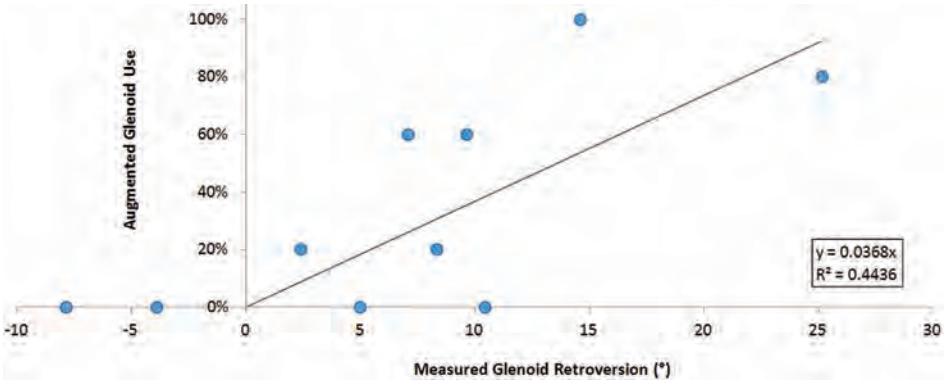

Figure 3 Use of augmented glenoids as a function of measured retroversion. Beyond 10° of retroversion most surgeons select an augmented implant to help preserve chondral bone.

Table 1 Preferred Position and Orientation of Glenoid Implant Using Two Different Planning Systems*

	AP Glenoid Center (+ anterior)	SI Glenoid Center (+ superior)	Glenoid Version (+ anteversion)	Glenoid Inclination (+ superior tilt)
3D Scapula Data (no augment prostheses available)	0.41 mm ± 1.09 mm	0.69 mm ± 1.65 mm	-8.88° ± 4.69°	4.35° ± 6.04°
Preoperative Planning Data (with augmented options)	-0.07 mm ± 0.42 mm	0.44 mm ± 0.82 mm	-0.96° ± 3.04°	3.26° ± 4.25°
P-value (t-test)	0.07	0.54	**< 0.001**	0.48

*P-values for unpaired t-test shown. Bold indicates statistical significance.

components allowed for preservation of subchondral bone and reduction in the need for reaming. There was a weak correlation between the use of augmented implants and preoperative retroversion ($R^2 = 0.4436$), but further data will be required to determine statistical significance (Fig. 3).

Discussion

According to the data acquired from the cadaveric portion of the study, assessment of the glenoid center and the neutral axis are challenging. The positional error of 1.69 mm ± 1.58 mm anterior and 1.99 mm ± 2.49 mm superior and orientation error of 11.8° ± 7.9° retroverted and 14.2° ± 9.2° of superior tilt are far greater than the spread of the data using the preoperative planning tool.

Previous studies have shown that malalignment greater than 10° can affect stresses in the implants and potentially postoperative function.[7-9] When given the 3D reconstruction of the scapula and a standard pegged glenoid option, the desired placement of the implant is on average closer to the neutral axis than what was assessed clinically. However, some retroversion was accepted in these implant placements to preserve subchondral bone, hence, the average retroversion of 8.88° instead of 0°.

When given the full range of glenoid options along with the added ability to see the scapular coordinate system and the CT scan overlaid with the 3D reconstruction, the final implant position was nearer to the neutral axis than what was measured in the 3D reconstruction study (closer to neutral in terms of position and orientation but only the retroversion reached statistical significance). The factors affecting glenoid placement are listed in Table 2 along with the potential clinical implications. These factors are evidenced by the planned placement of the glenoid with and without the availability of augmented options. The portion of our study utilizing the preliminary software without augmented glenoid options found that a greater amount of retroversion was considered acceptable when weighed against the additional bone loss required to correct. In the portion of our study utilizing the novel software with augmented glenoid options, the retroversion was generally corrected back to neutral through a combination of reaming and augmented glenoid options.

Conclusions

The expansion of new preoperative planning technology into shoulder arthroplasty may provide insight to guide

Table 2 Description of Factors Affecting Preoperative Implant Placement

Preoperative Consideration	Variables Affected	Clinical Implications
Bony Coverage	Implant Position (AP and ML) Implant Rotation (Rotation in the plane of the glenoid face) Implant Size	Largest contact area between glenoid implant and underlying bone to minimize bone stress and reduce risk of subsidence. Prevent implant overhang of the glenoid to reduce the risk of soft tissue or bony contact with the polyethylene.
Fixation with the Scapula Body	Implant Position (AP and ML) Implant Rotation (Rotation in the plane of the glenoid face) Implant Version Implant Inclination Depth of Reaming	Placement of implant in the center of the cancellous bone structure provides best potential for cement interdigitation or bone ingrowth depending on implant selected.
Version Correction	Implant Version Implant Type (Augmented?) Depth of Reaming	Improper retroversion of the implant associated with higher stresses in the polyethylene and cement. Residual retroversion of the glenoid greater than 10° associated with reduced clinical outcomes.
Bone Preservation	Implant Version Implant Inclination Implant Type (Augmented?) Depth of Reaming	Over-reaming has been associated with glenoid implant subsidence due to the loss of subchondral bone.

intraoperative decision making. However, based on the data in this study, intraoperative guidance must be provided to execute these plans effectively. The error associated with a free-hand technique for identifying the neutral axis of the scapula in cadavers was greater than 10° in both version and inclination, making it difficult to accurately place an implant as planned without intraoperative guidance. The shoulder joint is primarily soft-tissue balanced, and while these planning tools can help guide position and orientation, they have little ability to predict the response of these tissues. Hence, the subtleties of proper joint tension remain in the hands of the surgeon.

Distribution of Glenoid Implant Options for Correcting Deformities Using a Preoperative Planning Tool

Alexander Greene, B.S., Richard B. Jones, M.D., Thomas W. Wright, M.D., Ira M. Parsons, M.D., Paul Saadi, M.D., Emilie V. Cheung, M.D., Sandrine Polakovic, M.S., and Matthew A. Hamilton, Ph.D.

Abstract

Preoperative planning tools in shoulder arthroplasty are a recently developing technology with the advantage of being able to clearly assess patient anatomy and deformities before entering the OR. Addressing retroverted glenoids remains one of the most difficult aspects of primary shoulder arthroplasty. In this study, five surgeons were provided with a preoperative planning tool with posterior augmented glenoid implant options (0°, 8°, and 16°) to treat 10 cadaveric cases with a range of versions from 7.8° anteversion to 25.1° retroversion. Surgeons were able to remove less bone using 8° augmented implants over standard non-augmented implants (2.8° reamed vs. 6.4° reamed) and were able to correct each case on average within ± 1.8° of neutral version. Slight glenoid vault perforation was observed in 18% of the plans. Eight degrees posterior augmented implants were used in scans averaging 9.0° retroversion, and 16° posterior augmented implants were used in scans averaging 20.6° retroversion. Results were then compared to 14 preoperative CT scans provided by one of the surgeons in which both 8° and 16° posterior augmented glenoid implants were used in actual patients, showing 8° posterior augmented implants were used in cases averaging 12.3° retroversion, and 16° posterior augmented implants were used in cases averaging 20.7° retroversion. The study shows that surgeons can effectively and predictably use a preoperative planning tool to correct glenoid abnormalities using augmented implant solutions while minimizing both scapular bone removal and vault perforation and maximizing version correction.

Addressing difficult glenoid morphologies remains one of the greatest challenges in anatomic total shoulder arthroplasty (aTSA). Numerous studies have reported compromised results with aTSA in the presence of significant posterior glenoid bone loss.[1-4] Shapiro and coworkers found that placement of the glenoid component in 15° of retroversion resulted in decreased contact area of the glenohumeral joint and increased contact pressures in cadavers.[5] Farron and colleagues showed increased micromotion at the cement interface greater than 700% with retroversion over 10°.[6] Eccentric reaming to correct glenoid retroversion can result in bone loss and a medialized joint line, leading to instability and muscle inefficiency post-surgery.[4,7] Augmented glenoid options may be beneficial to correct glenoid retroversion and restore the natural joint line.[8-12]

Assessing glenoid deformity intraoperatively can be a difficult task. A combination of eccentric glenoid reaming and an augmented implant can be used, but the point at which wear is great enough to necessitate the use of an augmented implant is uncertain. In addition, computer aided preoperative planning tools are a relatively new technology, particularly in shoulder arthroplasty, and are an unknown in their accuracy and ability to execute a preoperative plan in the clinical setting.[13-18] The benefit of a preoperative planning tool is the ability to accurately visualize patient anatomy and deformities before surgery and specifically select an implant type and position that best addresses that deformity.

The purpose of this study is two-fold: 1. to quantify both the distribution of and point at which augmented glenoid solutions are used when a preoperative planning tool is

Greene AT, Jones RB, Wright TW, Parsons IM, Saadi PD, Cheung EV, Polakovic SV, Hamilton, MA. Distribution of glenoid implant options for correcting deformities using a preoperative planning tool. Bull Hosp Jt Dis. 2015;73(Suppl 1):S52-6.

provided and 2. to assess the ability to reconstruct various amounts of glenoid version using a preoperative tool utilizing augmented implant options and eccentric reaming with the goal of minimizing glenoid vault perforation.

Methods

Five orthopaedic shoulder surgeons (RJ, TW, IP, PS, and EC) were provided with 10 CT scans containing a range of glenoid versions, from 7.8° anteversion to 25.1° retroversion. CT Scans were reconstructed into 3D models using Mimics® software (Materialise, NV, Leuven, Belgium), and 3D measurements for both glenoid version and inclination were taken using Geomagic Design™ X software (3D Systems, Rock Hill, SC). Reconstructions were then imported into the Exactech GPS® software (Blue Ortho, Grenoble, France) for preoperative planning and implant placement as shown in Figure 1. Surgeons were able to vary glenoid implant size (small, medium, large, and extra-large), inclination, version, rotation, depth, and superior-inferior (SI) and anterior-posterior (AP) placement in positioning the implants. For the augmented glenoid options, surgeons were able to choose between implants with 0°, 8°, and 16° of posterior wear correction. The surgeons were instructed to select and place the implants based on how they would perform the surgery. All five surgeons planned the same 10 cases independently, which provided a total of 50 data points.

To further assess the distribution of augmented glenoids used in a clinical setting, one surgeon (TW) provided 14 preoperative de-identified patient CT scans of aTSA cases and the resulting augments chosen for each case. Retroversion measurements were taken on these scans and compared to the augment chosen for the surgery. This distribution was then compared to the augment-retroversion distribution from the preoperative planning group.

Results

Augmented glenoid use is detailed in Figure 2, showing the amount of retroversion present prior to planning. Results show that augment use began at 7° retroversion with 100% use at 14°. The transition from 8° to 16° augment use began at 14°, and by 25° only 16° augments were used. Overall, 8° augments were used in cases averaging 9.0° retroversion, and 16° augments were used in cases averaging 20.6° retroversion. Table 1 details average preoperative versus postoperative version, as well as average amount of bone removed for each implant. There was a statistically significant difference between preoperative versions within implant types ($p \leq 0.05$). There was also a statistically significant difference between average reaming correction for the standard and 8° augmented implants, signifying that augmented glenoids components conserve more bone than standard glenoids components with eccentric reaming. Figure 3 details the amount of bone reamed per augment, showing that in every case more bone was removed using standard implants over their augmented counterparts. Implant perforation of the scapula occurred in 18% of the cases with no apparent

patterns. In the preoperative patient scan group shown in Figure 4, 8° augments were used in cases averaging 12.3° retroversion, whereas 16° augments were used in cases averaging 20.7° retroversion.

Discussion

Improved glenoid fixation is necessary to improve the long-term success of aTSA. Long-term stability of the glenoid has been shown to be influenced by the preservation of the subchondral plate, compaction of cancellous bone, and mechanical compression of cement.[19,20] This can be made possible by careful avoidance of vault perforation. In this study, the goal of the surgeons was to use either a standard or augmented pegged glenoid with or without eccentric reaming to correct the version as much as possible while trying to avoid penetrating the glenoid vault, as would be done in the operating room.

Within this group of surgeons, there appeared to be a consistent threshold for the use of augmented glenoids occurring around 9° retroversion. The use of augments was 100% by 14° retroversion. Eight degree augments were used in lower degrees of retroversion, while 16° augments began to be used at 14° of retroversion, and by 20° to 25° only 16° augments were used. It should be observed that the one major outlier in the study occurred in the 25° retroversion case, where one surgeon selected a standard implant instead of the 16° that

Table 1 Average Preoperative Versus Postoperative Versions and Degrees Reamed for Each Implant*

	Average Preoperative Version	Average Postoperative Version	Average Reaming Correction (ABS)
Standard (No Augment)	3.6° ± 7.6°	0.7° ± 3.5°	6.4° ± 3.5°
8° Augment	9.0° ± 3.6°	1.8° ± 2.2°	2.8° ± 2.0°
16° Augment	20.7° ± 5.6°	0.7° ± 1.5°	5.4° ± 3.8°
P-value Standard vs. 8°	0.0370	0.3451	0.0030
P-value Standard vs. 16°	0.0000	0.9726	0.4995
P-value 8° vs. 16°	0.0001	0.2681	0.0748

*Retroversion is denoted as positive and anteversion is denoted as negative.

the other four surgeons selected. Of note, was the ability to achieve greater correction at higher degrees of retroversion (> 14°) with augmented implant use combined with some levels of reaming versus eccentric reaming alone (Table 1, Fig. 3).

Statistically significantly more reaming was performed with non-augmented glenoid implants versus 8° augmented implants (Table 1, Fig. 3).[5,6,10] Multiple studies have shown that approximately 15° to 18° retroversion can be corrected with eccentric reaming before vault perforation occurs.[3,19,20] However, this can be implant specific and results in significant bone loss, possible violation of the subchondral plate, and joint line medialization. The surgeons performing the preoperative planning in this study selected to use augmented implants with various amounts of eccentric reaming to correct larger amounts of retroversion. This theoretically would allow less reaming of the native bone in the clinical setting, possibly preserving the subchondral plate of the glenoid. Findings from the data of 14 actual cases from one surgeon also showed augment use patterns consistent with the virtual planning results. At retroversions of approximately 8° to 15°, 8° augmented implants were used. Greater than 15° retroversion was corrected with 16° augments. In total, using a combination of augmented implants and eccentric reaming, the surgeons were able to correct version on average to a postoperative version of ± 1.8°.

The preoperative planning data did show that there was an 18% incidence of vault perforation. All were considered slight with only the edge of one peg perforating. This is likely due to the surgeon trying to predict the best case scenario to correct as much version as possible while settling for minimal perforation. It must be remembered that this software is used to predict how the surgery will be performed in the actual clinical situation. While not optimal, many surgeons may try to strike a balance by trading slight perforation to correct more version.

There are limitations to this study. It is possible that preoperative planning software does not always truly replicate the clinical situation in the operating room. Difficulties of exposure, patient size, and surgeon experience are not taken into account in this situation. An additional issue is the variance in the ability to preoperatively measure version from a CT scan, as well as intraoperatively estimate version.[18] Unlike the preoperative planning software, the vault is frequently unable to be visualized 360°. Those patients with larger glenoid retroversion will certainly have more difficult exposures. Also, placement of augmented glenoids can be technically demanding, and some surgeons may not have experience with their use.

Despite these weaknesses, this study demonstrates the strengths of the preoperative planning process. This software does allow the surgeon to visualize the glenoid vault in 360°. Implant sizes and augment size use can be predetermined, and the decision can be made of whether or not an aTSA or rTSA would be a better option. If glenoid reconstruction cannot be performed without significant bone loss or vault perforation, a rTSA could be selected preoperatively, saving valuable time in the OR. The surgeon can also visualize the optimal position of the implant to avoid perforation and have a better understanding of how much reaming can be performed to achieve correction. This preoperative planning combined with an intraoperative navigation system could allow for accurate glenoid reconstruction and implant positioning in the future.

Conclusion

This study demonstrates that surgeons can preoperatively plan glenoid preparation using the ExactechGPS® software and predictably use augmented implants in certain degrees of abnormal version while minimizing glenoid vault perforation. It is recognized that this does not necessarily equate to the exact clinical situation. Future work includes combining the preoperative planning phase with surgeons trying to execute those plans in the operating room, which could better define the accuracy of the preoperative planning process and patient outcomes.

Analysis of Glenoid Fixation with Anatomic Total Shoulder Arthroplasty in an Extreme Cyclic Loading Scenario

Christopher P. Roche, M.S., M.B.A., Cameron Staunch, B.S., William Hahn, B.S., Sean G. Grey, M.D., Pierre-Henri Flurin, M.D., Thomas W. Wright, M.D., and Joseph D. Zuckerman, M.D.

Abstract

Introduction: ASTM F2028-14 was adopted to recommend a cyclic eccentric glenoid edge loading test that simulates the rocking horse loading mechanism beleived to cause aTSA glenoid loosening. While this method accurately simulates that failure mechanism, the recommended 750 N load may not be sufficient to simulate worst-case loading magnitudes, and the recommended 100,000 cycles may not be sufficient to simulate device fatigue-related failure modes. Finally, if greater loading magnitude or a larger number of cycles is performed, the recommended substrate density may not be sufficiently strong to support the elevated loads and cycles. To this end, a new test method is proposed to supplement ASTM F2028-14.

Methods: A series of cyclic tests were performed to evaluate the long-term fixation strength of two different hybrid glenoid designs in both low (15 pcf) and high (30 pcf) density polyurethane blocks at elevated loads relative to ASTM F2028-14. To simulate a worst case clinical condition in which the humeral head is superiorly migrated, a cyclic load was applied to the superior glenoid rim to induce a maximum torque on the fixation pegs for three different cyclic loading tests: 1. 1,250 N load for 0.75 M cycles in a 15 pcf block, 2. 1,250 N load for 1.5 M cycles in a 30 pcf block, and 3. 2,000 N load for 0.65 M cycles in a 30 pcf block.

Results: All devices completed cyclic loading without failure, fracture, or loss of fixation regardless of glenoid design, polyurethane density, loading magnitude, or cycle length. No significant difference in post-cyclic displacement was noted between designs in any of the three tests. Post-cyclic radiographs demonstrated that each device maintained fixation with the metal pegs within the bone-substitute blocks with no fatigue related failures.

Discussion: These results demonstrate that both cemented hybrid glenoids maintained fixation when tested according to each cyclic loading scenario, with no difference in post-cyclic displacement observed between designs. The lack of fatigue-related failures in these elevated load and high cycle test scenarios are promising, as are the relatively low displacements given the extreme nature of each test. This cyclic loading method is intended to supplement the ASTM F2028-14 standard that adequately simulates the rocking horse loading mechanism but may not adequately simulate the fatigue-related failure modes.

Orthopaedic manufacturers utilize various laboratory testing methodologies to simulate clinical failure modes under worst-case loading conditions to ensure safety and efficacy and also extrapolate long-term viability of medical devices prior to market release. Various testing standards and guidance documents have been approved to standardize methodologies and minimize patient risk while facilitating regulatory oversight for product clearances in the various worldwide markets for different implants. These testing standards often recommend worst-case loading conditions, explain how to set-up the test and measure particular variables, and specify minimum loading magnitudes along with minimum sample sizes; however, specific acceptance criteria are not always defined. For designers of anatomic total shoulder arthroplasty (aTSA)

glenoid implants, ASTM F2028-14[1] was adopted in 2000 to recommend a cyclic eccentric glenoid edge loading test method to simulate the rocking horse loading mechanism.[1,2] Aseptic glenoid loosening is well documented in the literature,[3-13] and numerous studies have been conducted[14-19] using this method to simulate the rocking horse failure mechanism.[3-19]

While this cyclic eccentric loading method accurately simulates the rocking horse loading mechanism, the minimum loading requirements recommended by the testing standard (750 N axial load as the humeral head is translated to ± 90% of the subluxation distance to induce shear and a resultant load between 800 N and 1,000 N depending upon the articular constraint of the tested device)[1] may not be sufficient to simulate worst-case loading magnitudes. Recent work by Westerhoff and coworkers using an instrumented shoulder prosthesis has demonstrated that joint reaction loads in excess of 1,700 N and 238% body weight (BW) have been reported during common activities of daily living in patients with total shoulder arthroplasty.[20-23] Furthermore, while the 100,000 cycles recommended by the standard may be sufficient to assess the fixation of the bone-cement interface, 100,000 cycles may not be sufficient to simulate device fatigue-related failure modes. Over the last decade, there have been a troubling number of reports in the literature of newer glenoid prosthesis designs removed from the market due to such device fatigue-related failure modes—each of these devices were likely tested to ASTM 2028 prior to release.[24-30] Assuming this cyclic eccentric test is performed using a greater loading magnitude or for a longer number of cycles, then the density of the polyurethane substrate utilized should be reevaluated as the specific density recommended by the standard (20 pcf)[1,14-16] may not be sufficiently strong to support the elevated loads and cycles.

The purpose of this study was to evaluate the long-term fixation strength of two different glenoid implant designs in both low (15 pcf) and high (30 pcf) density polyurethane bone-substitute blocks at elevated loads relative to the ASTM F2028-14 test. To simulate a worst case clinical condition in which the humeral head is superiorly migrated, we applied a cyclic load to the superior rim of each glenoid component inducing a maximum torque on the fixation pegs for each of the following three cyclic loading tests: 1. 1,250 N load for 0.75 M cycles in a low density (15 pcf) block, 2. 1,250 N load for 1.5 M cycles in a high density (30 pcf) block, and 3. 2,000 N load for 0.65 M cycles in a high density (30 pcf) block.

Methodology

Two different XL hybrid cemented cage glenoid designs were evaluated. The first hybrid cemented cage glenoid design consists of a net compression molded Ultra High Molecular Weight Polyethylene (UHMWPE) articular body assembled in the cleanroom using a pneumatic press to a modular Ti-6Al-4V plasma coated central cage peg and three Ti-6Al-4V peripheral pegs; this device has been used clinically with success since 2011 (Fig. 1). The second hybrid cemented cage glenoid design utilized identical material, locking mechanism geometry, and cleanroom assembly process as the first and was released in 2015 with slightly modified metal peg geometry to improve the ease of manufacturability (Fig. 1).

Prior to performing each of the three cyclic tests, each glenoid implant was secured with PMMA bone cement (Cemex, Tecres, Inc.) into each aforementioned 76 mm x 57 mm x 48 mm polyurethane bone substitute block (Solid Rigid Foam, Pacific Research Laboratories). The peg pattern was identical for each glenoid design, and the same instrumentation was used to prepare each block. Each glenoid was then positioned in the testing apparatus so that a compression load was applied directly to the superior glenoid edge (Fig. 2).

Three cyclic loading tests were performed: 1. 1,250 N load for 0.75 M cycles in a low density (15 pcf) block (N = 3 of each glenoid design), 2. 1,250 N load for 1.5 M cycles in a high density (30 pcf) block (N = 3 of each glenoid design), and 3. 2,000 N load for 0.65 M cycles in a high density (30 pcf) block (N = 4 of each glenoid design). To establish a baseline displacement, a dial gauge quantified the initial displacement associated with each glenoid in each density block as a static load equal to the load applied for each cyclic test was applied to the superior glenoid edge at a rate of 100 N/sec. After this initial displacement was established for each glenoid, the cyclic load was applied in the same location on the superior glenoid edge for a rate of 2 Hz. Following cyclic loading, a dial gauge quantified the post-cyclic displacement in the same method as the pre-

Figure 1 Equinoxe® cage glenoids (Exactech, Inc., Gainesville, FL); Left: "current" design used since 2011 and Right: "new" design used since 2015.

Figure 2 Representative image depicting cyclic loading along the superior glenoid rim when loaded at 2000 N. Superior glenoid rim plastic deformation is evident at these elevated loads.

cyclic displacement at a rate of 100 N/sec. After all glenoid implants were cyclically loaded, each device was analyzed for cracks at the implant-cement interface and radiographed. A two tailed unpaired, Student's t-test was used to compare mean pre- and post-cyclic displacements, where $p < 0.05$ determined significance.

Results

All devices completed cyclic loading without failure, fracture, or loss of fixation regardless of glenoid design, polyurethane density, loading magnitude, or cycle length. The pre- and post-cyclic displacement data from each of the three cyclic loading tests are presented and compared in Tables 1, 2, and 3, respectively. No statistically significant difference in post-cyclic displacement was noted between designs in any of the three tests. Additionally, Figures 3 and 4 depict representative radiographs of each cage glenoid design after cyclic loading along the superior glenoid rim; these radiographs demonstrate that each device maintained fixation with the metal pegs within the bone-substitute blocks and that no fatigue-related failures occurred with the metal pegs or the UHMWPE locking mechanism.

Discussion

The results of this study demonstrate that both new and current cage glenoid designs maintain fixation when tested according to each of the three different cyclic loading scenarios, with no difference in post-cyclic displacement observed between designs. The lack of fatigue-related failures observed in these elevated load and high cycle test scenarios are promising, as are the relatively low displacements given the extreme nature of each test. However, these laboratory results cannot fully predict the long-term clinical

P-value	0.3061	0.2676

performance of this novel hybrid cemented cage glenoid prosthesis. Similarly, we are not recommending this cyclic test be performed as a substitute for the ASTM F2028-14 standard as that test adequately simulates the rocking horse loading mechanism; instead, this testing methodology is recommended to supplement that testing standard to better characterize the long-term loading and fatigue performance of novel glenoid devices.

This cyclic study has some limitations. It utilized two different densities of polyurethane bone substitutes instead of cadaveric or composite scapula bone; this was done to improve uniformity and permit a better comparison between tested glenoid designs. Additionally, this study did not utilize a spherical humeral head to apply the load but rather applied the load through a 5/8 inch machine screw. Due to these elevated loads and high cycles, we observed plastic deformation along the superior rim of nearly every glenoid tested at 2,000 N; an improvement to this study would be to apply the load through a humeral head prosthesis to better distribute the pressure and limit the deformation. Additionally, because the cyclic load was only applied along the superior glenoid rim of each component, we did not alternate loading positions between the superior and inferior glenoid as is recommended by the ASTM F2028-14 test method in which the humeral head is translated ± 90% of the subluxation distance; thus, we did not explicitly simulate the rocking horse mechanism. However, it should be noted that by simulating a superiorly migrated humeral head, we applied the load more than 18 mm superior to the central axis of the glenoid at a significantly greater load than occurs with the ASTM F2028-14 test to induce a greater moment on the fixation pegs. This 18 mm eccentric loading position is considerably greater than the typical ± 5 mm position which occurs with the ASTM F2028-14 test where the maximum published displacement was less than ± 10 mm. A final limitation is that we did not cyclically load any device to failure; rather, we stopped the test at predefined cycles as described previously.

Future work using this cyclic loading method should run glenoids out to failure at different loads in different densities to establish true fatigue curves for different designs and substrates. This test can also be modified to simulate different clinical situations that have previously shown to predispose the glenoid component to a greater risk of loosening, such as implanting the glenoid in superior tilt, retroversion, or partially unsupported as could occur clinically when a surgeon uses a glenoid with partial eccentric reaming in a severely eroded scapula.[19,31] Additional testing configurations should quantify glenoid fixation when the fixation holes

are drilled off-axis or malpositioned to create nonuniform cement mantle thicknesses.[32,33] Future testing should also elucidate if different viscosities of PMMA bone cement or different methods of cement pressurization impact glenoid fixation.[34,35]

Conclusions

This study demonstrates that the novel hybrid cemented cage glenoids tested in three different cyclic loading scenarios maintain fixation without failure or fracture regardless of polyurethane density, loading magnitude, or cycle length. These laboratory results are promising, particularly given the extreme nature of the loading conditions; however, these results are not a substitute for long-term clinical follow-up, which is necessary to demonstrate the long-term viability of this device. The cyclic loading method presented in this study is intended to supplement the ASTM F2028-14 testing standard that adequately simulates the rocking horse loading mechanism but may not adequately simulate the fatigue-related failure modes observed with some glenoid designs, which have been documented in the literature over the past decade.[24-30]

Impact of Posterior Wear on Muscle Length with Reverse Shoulder Arthroplasty

Christopher P. Roche, M.S., M.B.A., Phong Diep, B.S., Matthew A. Hamilton, Ph.D., Thomas W. Wright, M.D., Pierre-Henri Flurin, M.D., Joseph D. Zuckerman, M.D., and Howard D. Routman, D.O.

Abstract

The use of reverse total shoulder arthroplasty (rTSA) in patients with posterior glenoid wear can be challenging. Implanting a baseplate in the correct version may require significant eccentric reaming, which further medializes the joint line and results in greater rotator cuff muscle shortening. To restore the joint line, bone graft may be required, though it is associated with additional risks. As an alternative solution, augmented glenoid baseplates offer the potential to restore the joint line and improve rotator cuff muscle tensioning without the need for eccentric reaming or supplemental bone graft. To that end, this computer analysis quantifies the rotator cuff muscle length for standard and augmented rTSA when used in a normal and posteriorly worn glenoid. These results demonstrate that shortening of the rotator cuff occurred for both the standard and posterior augmented reverse shoulder designs with additional muscle shortening occurring in scapula with posteriorly worn glenoids. More anatomic rotator cuff muscle tensioning was observed with augmented glenoid baseplates. The use of posterior augmented glenoid baseplates has the potential to improve stability and better restore active internal and external rotation, a current limitation of rTSA. However, clinical follow-up is necessary to confirm these favorable biomechanical results.

The reverse shoulder inverts the anatomic concavities to restore stability to the unstable shoulder and inferiorly and medially shifts the center of rotation (CoR) to lengthen the abductor moment arms and elongate the deltoid to facilitate improvements in abduction and forward flexion.[1-5] However, medially shifting the CoR also translates the humerus medially, which reduces deltoid wrapping to decrease joint stability, and shortens rotator cuff muscles to reduce their ability to generate active internal and external rotation, a current limitation of reverse shoulder arthroplasty.[4-8] Despite these limitations, the recent clinical success of reverse shoulder arthroplasty (rTSA) has led to an exponential increase in its usage and also an expansion of its indications, including its use in fractures, revisions, and ever more challenging scenarios such as severe posterior glenoid wear.[1,9-13] rTSA, as compared to anatomic total shoulder arthroplasty (aTSA), has some potential to have better mid- and long-term outcomes in patients with severe posterior wear because the conforming reverse articulation may provide better joint stability for patients with a posterior subluxed humeral head.[10] Additionally, the uncemented metal rTSA baseplate with supplemental screw fixation may provide better long-term glenoid fixation in patients with severe posterior wear than a cemented aTSA glenoid due to the need to eccentrically ream the glenoid to correct the deformity.[10,14-16] Use of rTSA in patients with eroded glenoids and the technique of eccentric reaming further medializes the joint line and results in additional rotator cuff muscle shortening.[18-19] To better restore the joint line in scapulae with eroded glenoids, some surgeons may choose to bone graft the glenoid[10,20-25]; this, however, is associated with additional risks, including extra cost, surgical time, and most concerning, the increased risk of glenoid loosening due to graft resorption or fracture.[8,10,20-26]

As an alternative solution to better conserve glenoid bone, increase prosthesis surface contact area with cortical

bone, and better restore the native joint line when performing rTSA in eroded scapular morphologies,[18,19,27] Exactech has developed augmented glenoid baseplates (Fig. 1). These augmented implants, released in early 2011, are implanted with off-axis reaming rather than eccentric reaming and are intended to address superior, posterior, superior-posterior, and medial glenoid wear patterns. The purpose of this computer analysis is to quantify the impact of posterior wear on muscle length using standard and posterior augmented reverse shoulder arthroplasty during three different motions: abduction in the scapular plane from 0° to 80° and internal and external rotation with arm at side from 0° to 40° (Fig. 2).

Methods

A 3D computer model was developed in Unigraphics (Siemens, Inc.) to quantify muscle length during abduction and internal and external rotation using a standard and 8° posterior augmented reverse shoulder (Equinoxe®, Exactech, Inc.) in both a normal and posteriorly worn glenoid. This muscle model has been utilized previously to compare the impact of different prosthesis designs, glenoid bone deformities, humeral implantation techniques, and glenoid implantation techniques on muscle lengths, deltoid wrapping, and muscle moment arms.[6-8,19,28-33] Each of these implants were geometrically modeled and implanted in a 3D digitized scapula and humerus (Pacific Research, Inc.) so that each glenoid

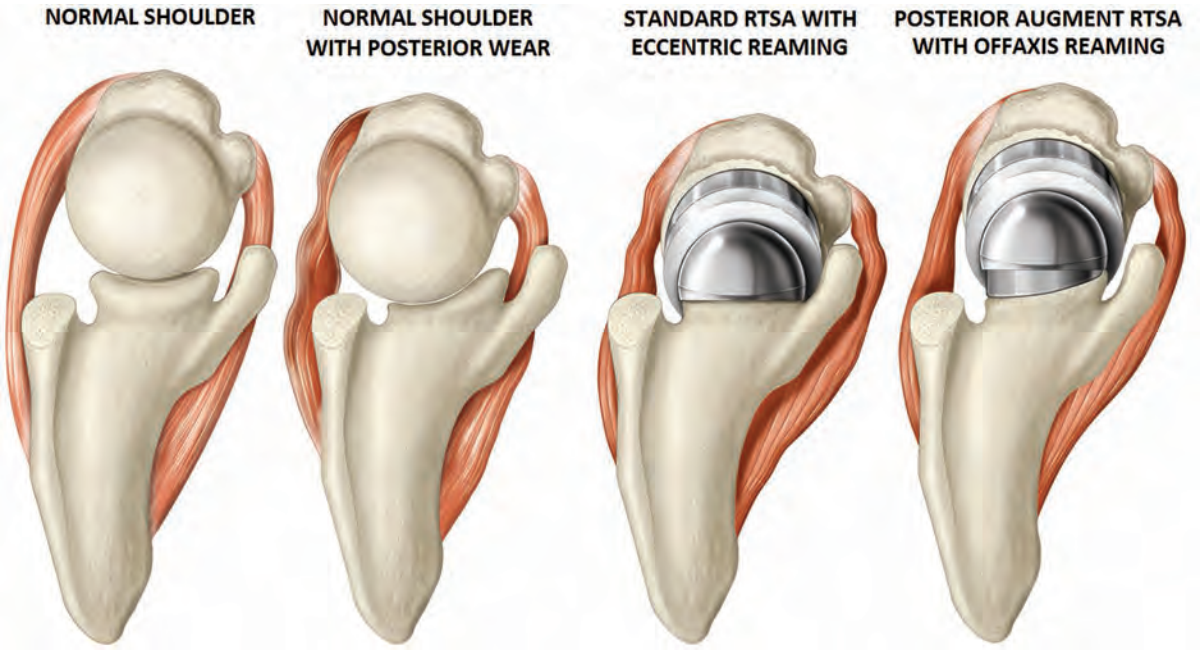

Figure 2 Muscle shortening and joint medialization with posterior glenoid wear: standard and posterior augmented rTSA.

baseplate aligned with the inferior glenoid rim as the humeral component was oriented in 20° retroversion. A posterior glenoid defect was created in the digital scapula by posteriorly shifting the humeral head by 11 mm (until greater tuberosity impingement with acromion), superiorly shifting the humerus by 1.5 mm, and then medially translating the humeral head by 7.0 mm into the scapula. The computer model included seven muscles that were simulated as three lines from origin to insertion: anterior deltoid, middle deltoid, posterior deltoid, subscapularis, infraspinatus, teres major, and teres minor. After assembling each implant in the normal and posteriorly worn scapula, the humeral component was abducted from 0° to 80° in the scapular plane relative to a fixed scapula and then internally and externally rotated from 0° to 40° with the arm at the side (i.e., 0° abduction). Muscle lengths were measured as the average length of the three lines simulating each muscle at each degree of motion; each muscle length, for each prosthesis, at each angle of motion was compared at the corresponding arm position for the normal shoulder to quantify the percentage change in muscle length relative to the anatomic configuration without posterior wear.

Results

The average change in muscle length associated with the standard and posterior augmented reverse shoulder during each of the three motions are presented in Tables 1, 2, and 3. For each of the three motions, both the standard and posterior augmented reverse shoulders elongate the anterior, middle, and posterior deltoid and shorten both the internal rotators (subscapularis and teres major) and the external

rotators (infraspinatus and teres minor) relative to the normal anatomic shoulder. For the standard reverse shoulder, both the internal and external rotators were shortened more by posterior wear. However, the posterior augmented reverse shoulders (regardless of posterior wear) kept the humerus more lateral and were associated with the least shortening of both the internal and external rotators.

Discussion

The results of this study demonstrate shortening of the rotator cuff for both the standard and posterior augmented reverse shoulder designs, with additional muscle shortening occurring in scapulae with posteriorly worn glenoids. More anatomic rotator cuff muscle tensioning was observed with augmented glenoid baseplates. The observation that the posterior augmented baseplate when used with posterior wear achieved more anatomic tensioning than the posterior augment baseplate when used in a normal scapula was unexpected; however, further investigation demonstrated that the posterior augmented baseplate removed less anterior bone to correct posterior wear than did the posterior augmented baseplate when used without wear. Thus, the posterior augmented baseplate when used with posterior wear achieved the most lateral humeral position in this computer model, resulting in greater muscle tensioning of the internal and external rotators. These improvements in muscle tensioning offer the potential to achieve greater stability and increase internal and external rotational motion and strength with augmented rTSA. However, clinical follow-up is required to confirm these favorable biomechanical results. This study was limited by its evaluation of muscle length in only one digital anatomy; future work should evaluate the impact of these designs in both normal and eroded scapula in multiple different anatomies.

Conclusions

This computer analysis provides new biomechanical insights on the use of rTSA in scapular with posterior wear. Additionally, the use of posterior augmented glenoid baseplates with and without posterior wear resulted in more anatomic tensioning of the rotator cuff muscles; this information is useful to the surgeon to potentially improve stability and restore active internal and external rotation, a current limitation of rTSA.

Glenohumeral Anatomic Study

A Comparison of Male and Female Shoulders with Similar Average Age and BMI

Amanda Jacobson, B.S., Gregory J. Gilot, M.D., Matthew A. Hamilton, Ph.D., Alexander Greene, B.S., Pierre-Henri Flurin, M.D., Thomas W. Wright, M.D., Joseph D. Zuckerman, M.D., and Christopher P. Roche, M.S., M.B.A.

Abstract

Introduction: Numerous anatomic studies of the shoulder have quantified the size, shape, and variability of either the humerus or scapula individually. However, few have attempted to quantify the relationship of the humerus to the scapula to better understand the spatial variation of these bones in both male and female shoulders.

Methods: Seventy-four cadaveric shoulder CT scans (37 males and 37 females with statistically equivalent age and BMI) were reconstructed using Mimics® to create 3D models of the humerus and scapula. After 3D reconstruction, each CT bone model was analyzed in Rapidform® to quantify the morphology of the humerus, scapula, and the spatial relationship between the two to better understand the role of gender on the morphological variability of the glenohumeral joint.

Results: Spatial glenohumeral relationships of male shoulders were significantly larger than female shoulders in 13 of 16 measurements; morphology of male humeri were significantly larger than female humeri in 17 of 24 measurements, and scapula and glenoid morphology of male shoulders were significantly larger than female scapula and glenoids in 11 of 22 measurements.

Discussion: Numerous significant gender differences in spatial relationships and morphology were identified in this anatomic study of the glenohumeral joint. An improved understanding of these observed binomial distributions has utility for shoulder arthroplasty prosthesis design, computer navigation, and may also be useful to the orthopaedic surgeon during surgical preoperative planning.

Numerous anatomic studies of the shoulder have previously quantified the size, shape, and variability of either the humerus[1-7] or scapula[2,4,7-17] individually, and some have assessed the variability as a function of gender.[6,7,11,14,15] However, few studies[4,7] have attempted to quantify the relationship of the humerus to the scapula to better understand the spatial variation of these bones in both male and female shoulders. An improved understanding of the variability in this spatial relationship may have many applications related to shoulder arthroplasty prosthesis design, computer navigation, and surgical implantation techniques (as many complications associated with shoulder arthroplasty involve patient-specific factors). Additional considerations should be given to gender effects since the majority of shoulder arthroplasty is performed in females, with females being recipients for reverse shoulder arthroplasty (rTSA) approximately 65% of the time. To that end, we conducted an anatomic study on 74 3D CT reconstructions of the shoulder (37 males and 37 females) to quantify the morphology of the humerus, scapula, and the spatial relationship between the two to better understand the role of gender on the anatomic variability of the glenohumeral joint.

Materials and Methods

Seventy-four cadaveric shoulder CT scans, 37 males (76.7 ± 8.8 years; BMI = 23.7 ± 6.3) and 37 females (78.1 ± 10.9

Table 2 Comparison of Average Humeral Measurements: Female Versus Male

Anatomic Parameter (mm unless noted)	All Humeri	Female	Male	P-value (Male vs. Female)
Dimension 1: HH Diameter	46.8 ± 4.2	43.7 ± 2.3	49.9 ± 3.3	< 0.0001
Dimension 2: HH Thickness	19.5 ± 2.5	17.9 ± 1.9	21.0 ± 2.0	< 0.0001
Dimension 3: Distance from top of HH to Deltoid Insertion	139.1 ± 9.9	134.2 ± 7.6	143.9 ± 9.6	< 0.0001
Dimension 4: HH Neck Angle	134.5 ± 5.1	134.3 ± 5.2	134.6 ± 4.9	0.8069
Dimension 5: HH Medial Offset	8.1 ± 3.3	7.6 ± 3.0	8.7 ± 3.6	0.1423
Dimension 6: HH Posterior Offset	3.2 ± 2.3	2.5 ± 2.0	3.8 ± 2.4	0.0164
Dimension 7: Total HH Offset	9.0 ± 3.4	8.3 ± 2.8	9.7 ± 3.8	0.0709
Dimension 8: Center of HH to Lesser Tuberosity	25.3 ± 3.5	22.9 ± 2.7	27.8 ± 2.2	< 0.0001
Dimension 9: Center of HH to Greater Tuberosity	22.4 ± 2.7	21.1 ± 2.5	23.8 ± 2.1	< 0.0001
Dimension 10: HH Retroversion (degrees)	26.7 ± 12.1°	29.4 ± 11.1°	24.1 ± 12.7°	0.0610
Dimension 11: Humeral IM Diameter (75 mm)	14.0 ± 3.0	11.9 ± 2.1	16.2 ± 2.1	< 0.0001
Dimension 12: Humeral Outer Diameter (75 mm)	23.1 ± 3.5	20.4 ± 2.2	25.8 ± 2.4	< 0.0001
Dimension 13: Humeral IM Diameter (Deltoid Insertion)	10.6 ± 2.4	9.4 ± 2.0	11.7 ± 2.1	< 0.0001
Dimension 14: Humeral Outer Diameter (Deltoid Insertion)	21.4 ± 2.9	19.2 ± 1.8	23.5 ± 1.9	< 0.0001
Dimension 15: Humeral IM Diameter (150 mm)	10.4 ± 2.4	9.2 ± 1.8	11.5 ± 2.4	< 0.0001
Dimension 16: Humeral Outer Diameter (150 mm)	21.4 ± 2.9	19.2 ± 1.9	23.7 ± 1.9	< 0.0001
Dimension 17: Humeral IM Diameter (225 mm)	9.1 ± 1.9	8.5 ± 1.6	9.8 ± 1.9	0.0030
Dimension 18: Humeral Outer Diameter (225 mm)	19.2 ± 2.6	17.1 ± 1.7	21.2 ± 1.6	< 0.0001
Dimension 19: Humerus Length	321.1 ± 21.3	307.1 ± 15.8	335.1 ± 16.3	< 0.0001
HH Articular Surface Area (mm^2)	3465 ± 633	3003 ± 329	3926 ± 518	< 0.0001
Offset Between IM and Outer Diameters (Deltoid Tuberosity)	0.9 ± 0.5	0.8 ± 0.5	1.0 ± 0.5	0.1925
Offset Between IM and Outer Diameters (75 mm)	0.8 ± 0.5	0.8 ± 0.4	0.9 ± 0.5	0.2683
Offset Between IM and Outer Diameters (150 mm)	0.9 ± 0.6	0.8 ± 0.4	1.1 ± 0.7	0.0401
Offset Between IM and Outer Diameters (225 mm)	0.6 ± 0.3	0.5 ± 0.3	0.6 ± 0.3	0.0659

To quantify the spatial glenohumeral joint relationships, each reconstructed CT bone model was oriented with the humerus in 10° of abduction in the scapular plane and positioned to permit 3 mm space between the humeral head and glenoid to account for the thickness of the cartilage and labrum (Fig. 1). As described in Figure 2 and Table 1, 16 measurements were obtained to quantify the position of the humerus relative to the scapula in the scapular plane. These scapular plane spatial measurements were selected because they can be visualized and measured from anterior-posterior (AP) radiographs and therefore may be viable as preoperative planning parameters. The coefficient of variation of each measurement was quantified to assess the viability of each measurement to be taken from AP radiographs.

As described in Figures 3, 4, and 5, and Table 2, 24 measurements were obtained to quantify the morphology of the humerus independent of the scapula. The humeral shaft outer diameter (OD) and humeral intramedullary (IM) canal diameter were measured using a best fit circle at four different heights (75 mm, 150 mm, and 225 mm from the humeral head and also at the deltoid tuberosity). The linear offset between these best fit circles was also quantified but not depicted in the figures. The humeral head diameter was measured with a best fit sphere; the humeral head thickness was measured from a plane defining the anatomic neck, and the articular surface area was calculated using this sphere diameter and associated thickness. The medial, posterior, and total offset of the humeral head center were measured relative to the IM axis; the anterior and posterior distances from the humeral head center were also measured for the lesser and greater tuberosities, respectively. The humeral head neck angle was measured relative to the IM axis, and the humeral head retroversion was measured relative to the epicondylar axis.

As described in Figures 6 through 9 and Table 3, 22 measurements were obtained to quantify the morphology of the scapula and glenoid independent of the humerus. Glenoid height was measured linearly along the superior-inferior (SI) glenoid axis. Glenoid width was measured linearly at the upper third and lower third of the glenoid as a line perpendicular to that SI glenoid axis; ratios between glenoid height and width were also calculated. The glenoid articular surface area was measured digitally from the selected glenoid face. Glenoid articular curvature was measured with a best-fit

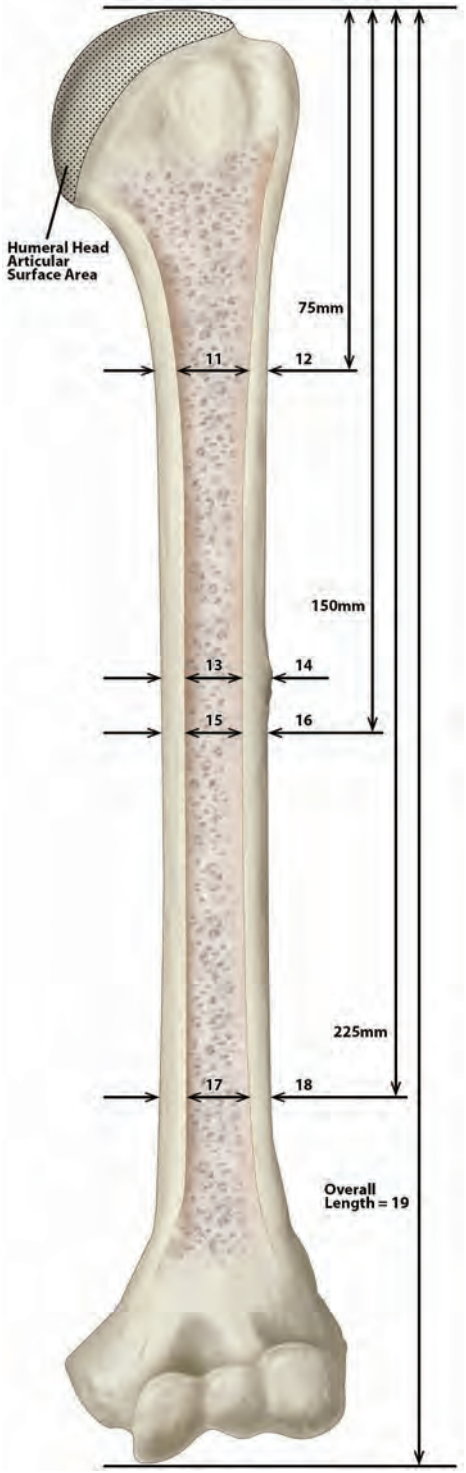

Figure 5 Humeral measurements 3.

sphere to the selected glenoid face. Glenoid neck length was measured linearly along the scapular plane between the inferior glenoid rim and the infraglenoid tubercule. Scapular neck angle was measured as the angular difference between the scapular neck and the SI glenoid axis. Glenoid version was measured as the angular difference between the anterior-posterior (AP) glenoid axis and the long axis of the scapula (defined by the line connecting the center of the glenoid and the intersection of the scapular spine and scapular body at the medial border); greater than 90° indicates retroversion. Similarly, glenoid inclination was measured as the angle between the long axis of the scapula and the SI glenoid axis; greater than 90° indicates inclination. Acromion length was measured linearly along the lateral border between its most anterior and posterior points. Acromion thickness was measured at two different locations: 1. SI width in the middle of the lateral border and 2. AP width at its intersection with the scapular spine. The posterior-superior (PS) acromion-glenoid distance was measured linearly in the AP direction between the most anterior point of the lateral border and the SI glenoid axis. The posterior-inferior (PI) acromion-glenoid distance was measured linearly in the AP direction between the most posterior point of the lateral border and SI glenoid axis. The lateral acromion-glenoid distance was measured linearly in the medial-lateral (ML) direction between the most lateral point of the lateral boarder and the center of the glenoid. The acromial-glenoid angle was measured as the angular difference between the lateral border and the SI glenoid axis. The coracoid tip-glenoid distance was measured linearly in the ML direction between the most lateral point of the coracoid to the center of the glenoid. Finally, the coracoid base-glenoid distance was measured linearly in the ML direction between the most lateral aspect of the coracoid base to the center of the glenoid.

Results

As described in Table 1, spatial glenohumeral relationships of male shoulders were significantly larger than that of female shoulders in 13 of 16 measurements. However, when each of the 16 glenohumeral relationship measurements were normalized by the humeral head diameter, only glenohumeral dimensions 8 and 10 were observed to be significantly different between male and female shoulders (with dimension 8 for male shoulders being significantly larger than female shoulders, and dimension 10 for female shoulders being significantly larger than male shoulders). These normalized measurements suggest that coracoid morphology is highly variable according to gender. Additionally, measurements 1 to 3, 9, 10, 13, 15, and 16 were all found to have coefficients of variations (COV) less than 15%, with dimensions 1, 2, and 16 having a COV between 6% and 8% for both male and female shoulders, suggesting that these scapular plane measurements are reliable and can be measured on AP radiographs.

As described in Table 2, measurements of male humeri were significantly larger than that of female humeri in 17 of 24 measurements. Male humeri were associated with significantly larger and thicker humeral heads that were more offset (particularly in the posterior direction) than female humeri. Additionally, male humeri were associated with significantly more anterior shift of the lesser tuberosity and significantly more posterior shift of the greater tuberosity. The male humeri were also observed to be significantly

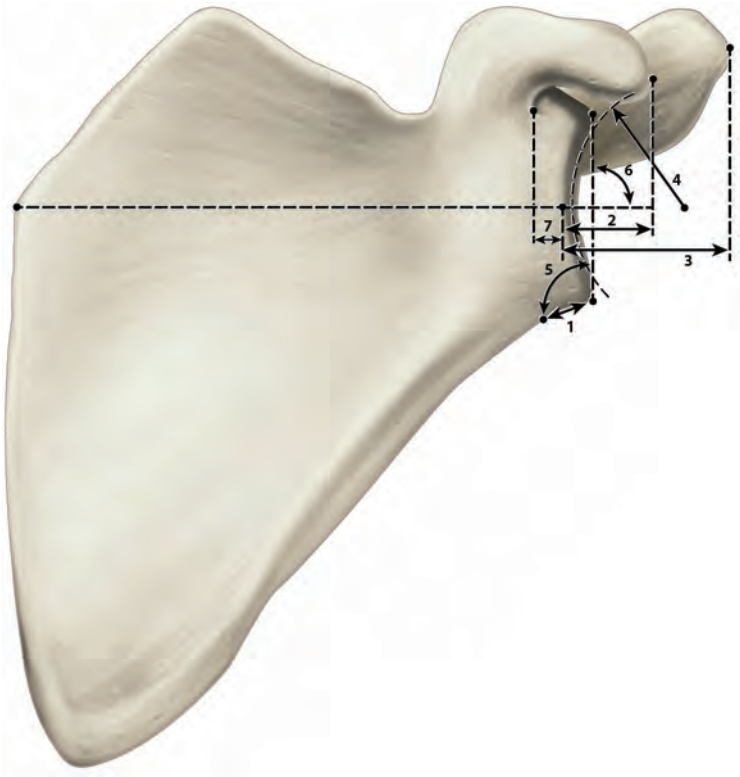

Figure 6 Scapula measurements 1.

longer, with larger OD and IM diameters at all four resection heights. However, when each measurement was normalized by the humeral head diameter, only humeral dimensions 8, 11 to 14, 16, 18, and humeral head articular surface area were observed to be significantly larger for male humeri than female humeri. When comparing the normalized measurements, humeral dimensions 3, 4, 10, and 19 were observed to be significantly larger for female humeri than male humeri.

As described in Table 3, scapula and glenoid measurements for male shoulders were significantly larger than that of female shoulders in 11 of 22 measurements. Male scapula were associated with significantly larger and wider glenoids than female scapula, with male glenoids having significantly larger articular surface areas. Additionally, male acromions

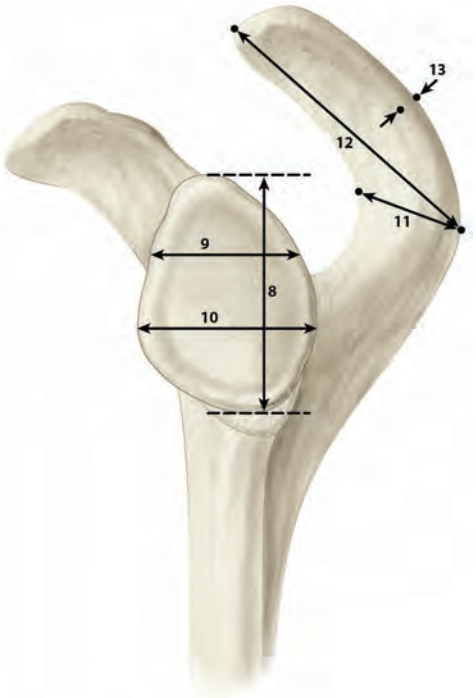

Figure 7 Scapula measurements 2.

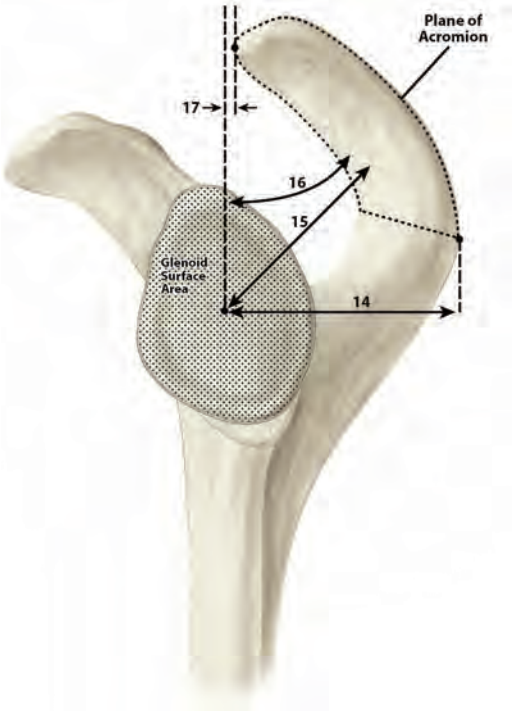

Figure 8 Scapula measurements 3.

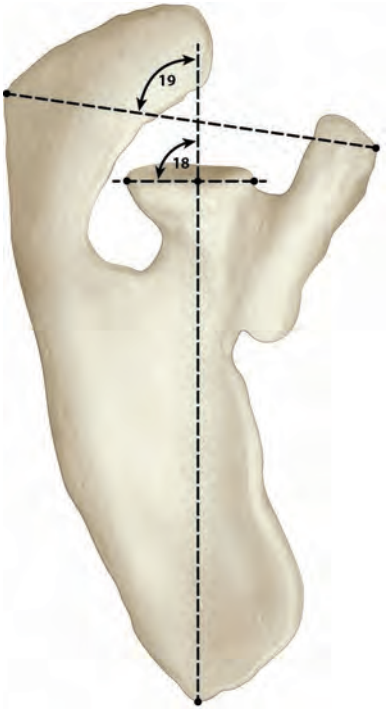

Figure 9 Scapula measurements 4.

were observed to be significantly thicker (both SI and AP) and longer than female acromions, with male acromions having significantly larger PI acromion-glenoid distances and lateral acromion-glenoid distances. Finally, male coracoids were observed to be longer than females, with males having longer coracoid tip-glenoid distances. However, when each measurement was normalized by the humeral head diameter, only scapula and glenoid dimensions 9, 11, and the glenoid articular surface area were observed to be significantly larger for male scapula than female scapula. When comparing the normalized measurements, scapula and glenoid dimensions 5, 6, 16, 18, 19, and both glenoid height and width ratios were observed to be significantly larger for female scapula than male scapula.

Considering only linear correlations greater than 0.9 between the direct (non-normalized) measurements, both males (r = 0.99) and females (r = 0.99) had a positive correlation between humeral head diameter (humeral dimension #1) and humeral head articular surface area. Additionally, both males (r = 0.97) and females (r = 0.95) had a positive correlation between humeral head medial offset (humeral dimension #5) and total humeral head offset (humeral dimension #7). Both males (r = 0.95) and females (r = 0.92) also had a positive correlation between the humeral intramedul-

Table 3 Comparison of Average Scapular Measurements: Female Versus Male

lary canal diameter at the location of the deltoid tuberosity (humeral dimension #13) and the humeral intramedullary canal diameter at a location of 150 mm inferior to the top of the humeral head (humeral dimension #15). Males were only observed (r = 0.91) to have a positive correlation between the lateral acromion and top of the greater tuberosity (glenohumeral joint relationship #4) and the lateral acromion and lateral greater tuberosity (glenohumeral joint relationship #6). Grouping male and female shoulders together demonstrated additional positive linear correlations greater than 0.9 between humeral dimensions #12 and #14 (r = .90), humeral dimensions #12 and #16 (r = 0.91), humeral dimensions #14 and #16 (r = 0.95), humeral dimensions #14 and #18 (r = 0.90), humeral dimensions #16 and #18 (r = 0.91), and finally scapular dimensions #8 and the glenoid articular surface area (r = 0.92).

Discussion

The results of this study demonstrate numerous gender differences in scapular plane glenohumeral joint spatial relationships, humeral morphology, and scapula and glenoid morphology. While many anatomic studies of the glenohumeral joint have been conducted previously,[1-21] the majority only quantify the morphology of one aspect, the humerus or the scapula or they evaluate both sides of the joint independently without quantifying the spatial relationships across the joint—particularly with respect to gender. One of the strengths of this study is that anatomic measurements were assessed on an equal number of male and female specimens, with each group having a statistically equivalent age and BMI.

These anatomic study results demonstrate that humeral morphology is highly variable with male humeri being significantly larger than female humeri in approximately two-thirds of the measurements. As described in Table 4, the means and standard deviations observed with our proximal humeral measurements are similar to that of previously published anatomical studies[1,3-7] of the humerus. These results also demonstrate that scapula morphology is highly variable with male scapula being significantly larger than female scapula in approximately one half of the measurements. As described in Table 5, the means and standard deviations observed with our glenoid, acromion, and coracoid measurements are similar to that of previously published anatomical studies[4,9-11,13-17,22] of the scapula. These comparisons both validate our results but also demonstrate (relative to Tables 2 and 3) that mean results by themselves can be misleading as numerous anatomic parameters of the humerus and scapula were observed to be binomial (due to gender). Two notable anatomic studies[4,7] have previously quantified a few of these measurements across the joint. Both Iannotti and coworkers[4] and Takase and associates[7] reported on the lateral humeral offset (e.g., glenohumeral joint relationship # 1). Iannotti and coworkers reported an average of 56 ± 5.7 mm, whereas Takase and associates reported an average of 62.3 mm ± 6.2 mm. Our results were nearly identical in magnitude and variability with that of Iannotti and coworkers. Additionally, our results on the glenohumeral offset (e.g., glenohumeral joint relationship # 2) were nearly identical in magnitude and variability to that of Takase and associates (55.7 mm ± 5.7 mm, M = 59.9 mm ± 3.6 mm, F = 50.7 mm ± 3.1 mm). When comparing the average measurement from the lateral acromion to the lateral greater tuberosity (e.g., glenohumeral joint relationship # 4) with the results of Takase and associates, there is a significant difference. Takase and associates reported 16.8 mm ± 5.9 mm, while the results of the current study found an average of 25.2 mm ± 4.9 mm. This mean difference can be attributed to different measurement techniques: specifically, Takase and associates positioned patients in the supine position with the arm in 0° abduction, 0° extension, and 0° of external rotation, while the current study positioned the arm in 10° abduction. Additionally, Takase and associates recorded measurements from radiographs, while the current study utilized digital CT scans.

These humeral measurements may be useful for biomechanical computer modeling and have implications on computer navigation and surgical implant positioning and also shoulder arthroplasty prosthesis design, particularly as each relates to soft tissue tensioning (given that, joint stability is best achieved and maintained after shoulder arthroplasty by restoring the native soft tissue tensioning, and native soft tissue tensioning is best restored by implanting a prosthesis that restores the patient's humeral anatomy).[1,5,6,19,23,24] Future work should evaluate if the observed anatomic variability of the proximal humerus in both male and female shoulders can be accommodated by contemporary "fourth generation" shoulder arthroplasty prostheses due to the observed binomial distribution of many of these humeral measurements.

These glenoid and scapula measurements may be useful for rTSA baseplate positioning (using standard instrumentation, patient-specific instruments, or computer navigation) to avoid scapular notching while also maximizing surface contact area in male and female patients. The recent expansion in usage of rTSA has led to new guidelines being established for implant positioning to avoid humeral liner impingement and scapular notching and aseptic glenoid loosening.[25-34] However, with few exceptions, shoulder arthroplasty implantation guidelines are generic[1,3,5-6,18-19,24,31,33] or specific[23,25,27-32,34,35] to individual prosthesis designs rather than to being specific to any particular gender or morphology. As the majority of rTSA recipients are female, rTSA baseplates should be designed to accommodate these smaller and thinner glenoids. Previous work has demonstrated that shorter glenoid necks and higher scapular neck angles predispose patients to a greater risk of scapular notching[25,27,30-32]; this study reports no significant difference in glenoid neck length or scapular neck angle between males and females and may explain why male and female scapular notching rates are reported to be similar.[30] Furthermore, several studies[25-32,34] have found that positioning the glenoid implant more distally can significantly improve range of motion and reduce the risk of notching regardless of

the patients scapular neck angle. However, little information is available regarding the minimum contact area necessary for rTSA baseplate fixation; this anatomic data on glenoid size and shape may be helpful to establish those limits.

These acromion measurements and glenohumeral joint spatial relationships may be useful to improve our understanding of shoulder kinematics, particularly related to how the deltoid moment arms change with gender and morphology. Acromion size and width were observed to be significantly different between male and female scapula; as the middle and posterior heads of the deltoid originate on the acromion and scapular spine, acromion size can influence the magnitude of the deltoid's moment arms, the degree of wrapping around the greater tuberosity of the humerus, and its line of action at various joint positions. In this study, male shoulders were noted to have significantly larger deltoid moment arms than female shoulders; however, no difference was noted in deltoid wrapping (as measured by the angle between acromion and the top of greater tuberosity). Acromial thickness was also observed to be significantly different between male and female scapula; this data relates to the strength of the acromion, and it may be useful to predict acromial stress fractures, a common complication of rTSA. Future work should investigate if certain acromion morphologies impart greater deltoid efficiency (e.g., larger deltoid moment arms) and determine if there is a minimum cross-sectional area required to prevent acromial and scapula stress fractures with rTSA. If so, these anatomic measurements may be a cost-effective preoperative surgical planning tool or a parameter utilized intraoperatively with computer navigation to predict functional performance and quantify a patient's rTSA complication risk.

Additionally, the coracoid position data relative to the glenoid and greater tuberosity may be useful for assessing medial glenoid wear. Previous work has demonstrated that glenoid wear can shorten the rotator cuff muscles with both aTSA and rTSA,[36-38] decrease deltoid wrapping with rTSA,[36] and also increase the instability rate with rTSA by causing the deltoid to distract the humeral component off the glenosphere.[36,39] Given that no difference was observed in the coracoid base-glenoid distance (scapula dimension #7) between male and female scapula, the mean and variation of this measurement may be useful for surgeons to identify medial glenoid wear preoperatively with AP radiographs or intraoperatively using computer navigation. Specifically, if the coracoid base-glenoid distance was measured and found

to be a negative number, it is likely that the patient has some amount of glenoid wear. Alternatively, as the coracoid position relative to the greater tuberosity of the humeral head (glenohumeral joint relationship #3) is very consistent (COV of 10.9% for females and 13.7% for males), this measurement may also be useful to identify medial glenoid wear preoperatively with AP radiographs or intraoperatively using computer navigation. Specifically, if the distance between the lateral coracoid and lateral portion of the greater tuberosity is measured to be two standard deviations from the mean (32.5 mm for males and 27.2 mm for females), it is likely that the patient has significant glenoid wear.

This anatomic study of male and female shoulders has several limitations. First, all measurements were made digitally from the 3D CT-reconstructed bone model rather than directly from the retrieved bones; additionally, measurements were made from the bone models and do not simulate the thickness of the articular cartilage. Second, the glenohumeral joint spatial relationships were measured by digitally manipulating each 3D reconstructed bone model to ensure all bones were positioned identically in 10° abduction with 3 mm between the humeral head and glenoid rather than externally positioning each patient identically at the time of imaging; as a result, some of the patient's passive relationships may have been slightly altered. Third, while the male and female CT scans were matched for age and BMI, information on race and ethnicity was not available and therefore could not be compared. Finally, no information was available on patient pathology; therefore, differences in morphology as a function of pathology could not be determined.

Conclusions

This CT reconstruction anatomic study of male and female shoulders demonstrates numerous significant gender differences in the morphological variability of the humerus, glenoid and scapula, and also the spatial relationship of these bones. An improved understanding of these observed gender differences has utility for shoulder arthroplasty prosthesis design, computer navigation, intra-operative implant and surgical positioning, and may also be useful to the orthopaedic surgeon during surgical preoperative planning.

Abstract

Introduction: Osteoarthritis of the shoulder often results in significant posterior glenoid wear. The options for treating this have been eccentric glenoid reaming and occasionally bone grafting. More recently reverse total shoulder arthroplasty (rTSA) with or without bone grafting and posterior augmented glenoids (PAGs) has been introduced. The PAG restores the native joint line while reaming a minimal amount of glenoid bone. The purpose of this study is to compare osteoarthritic shoulders with significant posterior glenoid wear treated with anatomic total shoulder arthroplasty (aTSA) using a PAG to shoulders without glenoid wear treated with aTSA using a standard all poly pegged glenoid.

Methods: The patients' data in this study were retrospectively queried from prospectively acquired data in a multi-institutional IRB approved database. The study population consisted of 24 patients with osteoarthritis and posterior glenoid wear who were treated with aTSA using a PAG with a minimum of two-year follow-up. This population was age, sex, and follow-up matched to patients treated with an all poly non-augmented pegged glenoid (NAG) for osteoarthritis. Seven females and 17 males with an average age of 65.8 ± 11.5 years received a posterior augmented glenoid. The control group consisted of 7 females and 17 males with an average age of 66.4 ± 9.1 years who underwent aTSA for osteoarthritis using an all poly standard glenoid. These age, gender, and follow-up matched patients were evaluated and scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI scoring metrics; active abduction, elevation, and external rotation were also measured. A Grashey and axillary lateral radiograph was evaluated at two-year follow-up. The Shoulder Arthroplasty Subluxation Index was used to determine the degree of humeral component subluxation on the glenoid component. A Student's two-tailed, unpaired t-test was used to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significant difference.

Results: All patients demonstrated significant improvements in pain and function with the primary aTSA. Sixty percent of PAG shoulders had a radiolucent line with an average radiographic line score of 1.10, and 33.3% of NAG had a radiolucent line with an average radiographic line score of 0.438. One glenoid in the PAG group is radiographically but not clinically loose. In the PAG group, the Grashey view showed that 18/20 humeral heads were centered with the two remaining joints demonstrating superior subluxation. On the axillary lateral in the PAG group, 17/20 humeral heads were centered, and three were anteriorly subluxated; none were posteriorly subluxated. There were no differences in any of the measured postoperative clinical outcomes or any difference in improvement between the two groups.

Discussion: At a minimum of two-year follow-up, there were no statistical clinical differences between the PAG and NAG groups despite the PAG group being disadvantaged with posterior worn glenoids. There were no revisions in either group. No humeral heads resubluxated posteriorly. The PAG group had a higher incidence of lucent lines. Based on this short-term follow-up, a posterior augmented glenoid is a viable option for the posterior worn osteoarthritic glenoid.

Osteoarthritis of the glenohumeral joint frequently causes posterior asymmetrical glenoid wear. The mechanism for this wear pattern is unknown. A plausible explanation is that the vast majority of activities of daily living occur with the arm in internal rotation, which can lead to tightening of the anterior capsule and posterior glenoid load concentration from the larger internal rotator muscles. With anterior capsular tightening, the humeral head moves posteriorly, and the articular cartilage experiences greater forces. The cartilage then fails with the result that the head subluxates posteriorly, the anterior capsule further tightens, and the posterior glenoid contact forces increase, resulting in posterior glenoid bone wear. Only the relatively weak shoulder external rotators (teres minor and infraspinatus) can attempt to balance the shoulder, and they are overwhelmed by the large internal rotation moment arm of the forearm and the massive internal rotation muscles (pectoralis major, teres major, and latissimus dorsi). Although not all osteoarthritis of the shoulder results in the classic biconcave posterior worn B2 glenoid,[1] much does. The B2 glenoid is a serious technical challenge for the operating surgeon.

Historically, the B2 glenoid was treated with benign neglect (hemiarthroplasty) and reaming the high side [anatomic total shoulder arthroplasty (aTSA)]. Both of these treatment options have their shortcomings; the hemiarthroplasty accelerates the glenoid wear, often remaining painful and not correcting the humeral glenoid posterior subluxation. Reaming the high side, while initially appealing for simplicity, removes a large amount of the best subchondral bone, which can result in loosening and medial migration of the glenoid component.[2-4] The purpose of this study is to introduce the preliminary results of a third option of aTSA using a posterior augmented all-polyethylene pegged glenoid.[5] The advantages of this posterior augment glenoid include the need for minimal glenoid reaming[6,7] while restoring the native joint line (Fig. 1). Equally important is the surgical technique for glenoid preparation and insertion, which will be presented in detail.

Materials and Methods

The patients' data in this study were retrospectively queried from prospectively acquired information in a multi-institutional IRB approved database. The study population consisted of 24 patients with osteoarthritis and posterior glenoid wear who were treated with aTSA using a posterior augmented glenoid (PAG) with a minimum of two-year follow-up (Fig. 2). This population was age, sex, and follow-up matched to patients treated with an all-polyethylene non-augmented glenoid (NAG) for osteoarthritis. Seven females and 17 males with an average age of 65.8 ± 11.5 years received a PAG. The control group consisted of 7 females and 17 males with an average age of 66.4 ± 9.1 years who underwent aTSA for osteoarthritis and received a NAG. These age, gender, and follow-up matched patients were evaluated and scored preoperatively and at latest follow-up using the Simple Shoulder Test (SST), University of California Los Angeles (UCLA), American Shoulder and Elbow Surgeons (ASES), Constant, and Shoulder Pain and

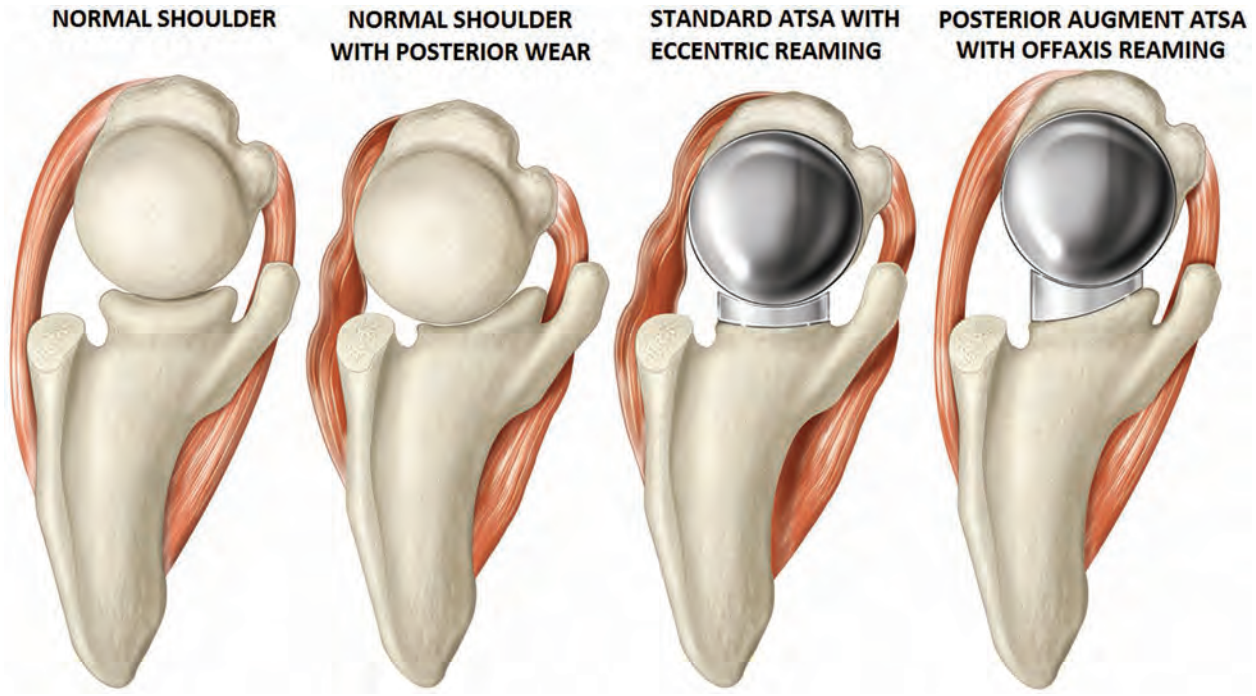

Figure 1 Use of posterior augmented glenoids to conserve glenoid bone and restore the joint line when correcting posterior defects with aTSA.

Figure 2 Equinoxe® 8° posterior augment pegged glenoid (Exactech, Inc., Gainesville, FL); left and right devices depicted.

Disability Index (SPADI) scoring metrics; active abduction, elevation, and external rotation were also measured. Internal rotation was measured by vertebral segments and was scored by the following discrete assignment: trochanter = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, Th12-Th8 = 6, and Th7 or higher = 7. The average follow-up for aTSA patients with a PAG was 29.4 ± 7.9 months, and the average follow-up for age and gender matched aTSA patients with a NAG was 29.6 ± 8.7 months. A Grashey and axillary lateral radiograph was evaluated at two-year follow-up. The Shoulder Arthroplasty Subluxation Index (SASI) was used to determine the degree of humeral component subluxation on the glenoid component (Fig. 3). The SASI uses the metallic central post marker, which is extended as a straight line and intersects the humeral head arthroplasty. The humeral head is divided into thirds on both the axillary lateral and Grashey views. If the line contacts the humeral head in the central third, the subluxation is neutral. On the axillary lateral, if the line contacts the arthroplasty head in the posterior one-third, then the head is anteriorly subluxated; the reverse is the case if it contacts the head in the anterior segment. On the Grashey view, if the line contacts the humeral head arthroplasty in the inferior one-third, then the head is subluxated superiorly, and the opposite is also true. A Student's two-tailed, unpaired t-test was used to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significant difference.

Results

All patients demonstrated significant improvements in pain and function following treatment with the primary shoulder arthroplasty. The database contained zero complications for the aTSA patients with a PAG and zero complications for the NAG cohort. Radiographic data were available for 20 of 24 PAG patients and 15 of 24 NAG patients. Twelve of 20 PAG patients had a radiolucent line (60.0%) with an average radiographic line score of 1.10. Five of 15 NAG patients had a radiolucent line (33.3%) with an average radiographic line score of 0.438. One glenoid in the PAG group

is radiographically loose but not clinically loose. In the PAG group, the Grashey view showed that 18/20 humeral heads were centered with the two remaining joints demonstrating superior subluxation. On the axillary lateral in the PAG group, 17/20 humeral heads were centered, and three were anteriorly subluxated; none were posteriorly subluxated. A typical patient preoperatively and 1 year postoperatively is shown in Figure 4; note the larger posterior space consistent with the PAG. Also note that the humeral head is not posterior subluxated as it was preoperatively. The average preoperative, postoperative, and preoperative to postoperative improvement for each glenoid type is presented in Tables 1, 2, and 3, respectively. There were no differences in any of the measured postoperative clinical outcomes or any difference in improvement between the two groups.

Surgical Technique

Computerized tomography (CT) scan is used for preoperative planning. The CT scan can estimate the degree of retroversion, the amount of humeral head subluxation, and the amount of posterior glenoid wear. In addition, it is useful to determine on the axillary cuts exactly where to place the starting hole for the central peg of the glenoid. Generally, the optimal central peg hole is at the B2 ridge or 1 mm behind it.

Once the glenoid is exposed, the starting point for the reamer or guide pin is determined usually at the center or slightly above in the superior inferior axis and anterior on the anterior posterior axis. Because the surgeon cannot see the glenoid tangentially, the tendency is to place the starting point too posterior; in other words, the eyes will play tricks with this acute angle view (the glenoid is facing away for the surgeon). The thumb makes an excellent measuring stick. The starting point must not be placed posterior. At this point, the surgeon can use the K-wire guide technique or ream-it-flat technique. My recommendation is the ream-the-glenoid-flat technique as it is simple and relatively fast. With this technique, the center hole is drilled only deep enough to place the nub of the reamer in place; this will allow the surgeon to lever the reamer posterior. The goal is to ream away the ridge and get a circle with the reamer but not to correct the retroversion. With this technique, minimal glenoid bone is removed. Once the glenoid has been reamed to the appropriate sized reamer, the 8° or 16° posterior augmented guide is placed, and the center hole is fully drilled with the appropriate angled guide on the reamed surface. Next, the peripheral augmented guide of the same degree is used to drill the peripheral holes. The glenoid is trialed, and if stable, the actual implant is cemented in place using the triple pressurization technique.[8] The humerus is then inserted in the standard fashion. Use of the shortest head is generally recommended. The joint will want to subluxate posterior, but this is easily corrected with the subscapularis repair and rotator cuff interval imbrication. The looser the joint, the more we close the rotator cuff interval towards the coracoid. Resubluxation or dislocation posterior has not been a problem.

If the surgeon opts for the K-wire guide technique, the K-wire is placed at the desired position for the central peg placement as described in the previous paragraph. The wire is advanced so as to come out just anterior and parallel to the glenoid neck, which the surgeon can palpate. The K-wire guide is then placed over this wire, and a second K-wire is placed through the 8° or 16° hole corresponding to the amount of correction desired. K-wire one is now removed, and a cannulated reamer is placed over K-wire two reaming the glenoid until flat. The K-wire guide is then replaced, and the K-wire one is reintroduced into its previous hole. K-wire two is now removed. A cannulated drill is then used to drill over K-wire one with subsequent removal of K-wire one. The 8° or 16° peripheral peg drill guide is then placed, and the peripheral holes are drilled. Glenoid preparation is now complete.

Discussion

The problem of posterior glenoid wear is a significant one associated with inferior clinical results and a higher revision rate when compared to arthritis associated with concentric glenoids.[1-3] Treatment of these complex patients has involved replacement of the humerus only or reaming the glenoid perpendicular (removing anterior glenoid bone) and then placing an aTSA. Both of these options have significant shortcomings, so much so that other options are now proposed, including the use of the augmented glenoid, bone grafting,[9] reverse total shoulder arthroplasty (rTSA),[10] and rTSA with bone grafting. Hemiarthroplasty leaves the joint subluxated and can increase glenoid wear as the metallic head is much harder than the native glenoid bone.[11] Reaming of the high side removes much of the best glenoid bone, resulting in component loosening and medial migration. If the glenoid component is left in retroversion greater than 10°, the humeral head will posteriorly subluxate; the contact forces will rapidly increase, and the glenoid component will loosen.[12]

Rice and coworkers[13] have the only reported series on posterior augmented glenoids. Their glenoid only corrected 5°, and the correction was all on the articular side, which left the pegs in a position to penetrate the anterior portion of the glenoid vault. Their results, however, were not particularly severe, even though they abandoned the use of that implant. Our study used new implants very different than the Cofield implant as the correction is on the boney side, which allows the pegs to remain in the glenoid vault. It is provided in multiple sizes to correct defects either 8° or 16° of retroversion (Fig. 2).

Radiographically, the rate of lucent lines was slightly higher than the control group without glenoid wear. No implant has been revised to date, though one is radiographically but not clinically loose. No humeral heads resubluxated posteriorly. Finally, clinically, there was no difference

between the PAG and NAG groups at two-year follow-up.

Conclusion

It is our opinion that in patients with up to 25° of glenoid retroversion who are relatively active, with reaming away the glenoid B2 ridge and placing the 16° augment, the joint line will be restored to within 5° of neutral. In more severe deformities consideration should be given to treatment with a rTSA using an augment or bone graft. In very low-demand patients, a rTSA may also be the best solution. Based on this short-term follow-up, a PAG is a viable option for active patients with a good rotator cuff and glenoid deformities of 25° of retroversion or less.

Preliminary Results of a Novel Hybrid Cage Glenoid Compared to an All-Polyethylene Glenoid in Total Shoulder Arthroplasty

Sean G. Grey, M.D., Thomas W. Wright, M.D., Pierre-Henri Flurin, M.D., Joseph D. Zuckerman, M.D., Richard Friedman, M.D., F.R.C.S.C., and Christopher P. Roche, M.S., M.B.A.

Abstract

Introduction: The aim of this study was to evaluate the preliminary outcomes of a hybrid cage glenoid design in comparison to pegged all-polyethylene glenoid components in anatomic total shoulder arthroplasty (aTSA).

Materials and Methods: Ninety-two patients undergoing primary anatomic total shoulder arthroplasty with minimum two-year follow-up were reviewed. Forty-six patients had an ultra-high molecular weight polyethylene (UHMWPE) cemented pegged glenoid component, and 46 had a hybrid cage glenoid component. Patient data was retrospectively reviewed from prospectively acquired data in a multi-institutional IRB approved database. These age, gender, and follow-up matched patients were evaluated and scored preoperatively and a latest follow-up using the SST, UCLA, ASES, Constant, and SPADI scoring metrics. Additional measures included active abduction, elevation, and external rotation. Radiolucent line assessment of the glenoid was performed by use of a Grashey and axillary radiograph at latest follow-up. A Student's two tailed, unpaired t-test was used to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significant difference.

Results: All patients demonstrated significant improvements in pain and function following treatment with the primary aTSA. The database contained three complications for the aTSA patients with a cage glenoid, and three complications for patients with a UHMWPE pegged glenoid. Radiographic data was available for 37 of 46 cage glenoid patients and 29 of 46 UHMWPE pegged glenoid patients. Five of 37 cage glenoid patients had a radiolucent line (13.5%) with an average radiographic line score of 0.22. Eight of 29 UHMWPE peg glenoid patients had a radiolucent line (27.6%) with an average radiographic line score of 0.57. Cage aTSA patients were associated with significantly less blood loss than aTSA UHMWPE pegged glenoid patients (avg. blood loss = 242 vs. 337; $p = 0.022$).

Conclusion: At minimum two-year follow-up, hybrid cage aTSA components show equal clinical outcomes to UHMWPE pegged glenoids. However, the hybrid cage components had significantly fewer radiolucent lines and less intra-operative blood loss. Additional and longer-term clinical and radiographic follow-up is necessary to confirm these promising early results.

While the overall success rate for anatomic total shoulder arthroplasty (aTSA) is good, glenoid-sided aseptic loosening remains the most common long-term complication.[1] Radiographic evidence of lucent lines has been reported to range from 22% to 95% in various types of glenoid implants.[2-8] Although a variety of glenoid designs exist in the USA at this time, all-polyethylene cemented peg glenoid designs remain the gold standard.[4-9] In these pegged all-polyethylene glenoid components, radiolucent lines are common and aseptic glenoid loosening remains the primary concern for longevity of the device.

This incidence of lucent lines and glenoid component loosening led to interest in a variety of metal-backed and bone in-growth devices.[4,10-13] Uncemented or limitedly cemented implants offer the potential to reduce the historical

aseptic glenoid loosening rate at longer term follow-up. A number of metal-backed uncemented designs have been conceived and are currently available in the USA and Europe. When compared to cemented all-polyethylene glenoids, previous metal-backed designs have shown higher failure rates for a variety of reasons.[4,10-13] Inclusion of metal backing results in relatively thin polyethylene and/or overstuffing of the joint. This decreased polyethylene thicknesses in combination with increased polyethylene contact pressures result in polyethylene fracture or accelerated wear rates, osteolysis, and ultimately loosening.[10] A number of metal-backed designs had no bone in-growth surface/coating; initial fixation was obtained with the use of screws. Lack of an in-growth surface led to eventual loosening of the screws under repetitive loads.[1] Trabecular metal and other highly porous materials/designs, in which there is no metal backing on the face of the glenoid, have shown excellent bone in-growth but have had problems with metal fracture and dissociation at the trabecular metal/polyethylene implant interface.[9] This has been accompanied by higher early revisions for aseptic loosening. Lack of peripheral pegs to control rotational forces between the trabecular metal and polyethylene may be a contributing factor.[9]

Limited cementing with all-polyethylene designs have shown some promise.[14-16] In this hybrid design, early fixation is obtained with a combination of peripheral peg cementation and interference fit of the central peg. Long-term fixation is supplemented with documented bone in-growth around the phalanges of the all-polyethylene central peg.[16] Some studies, however, have also shown radiolucency around the central peg, and there is concern that the flanges may not represent the best long-term surface for bone fixation.[17] The purpose of this paper is to study the 2-year minimum clinical outcome data of a new glenoid design which incorporates a bone through-growth commercially pure titanium plasma coated central cage connected to a 4 mm thick fully-molded all-polyethylene four pegged glenoid (Fig. 1). Early clinical and radigraphic results are presented, as well as the surgical technique.

Materials and Methods

After IRB approval, patient data from a prospectively acquired multi-institutional database was retrospectively reviewed. Participants in this study consist of 92 (average age: 63.2 ± 9.4 years) patients with an aTSA performed for osteoarthritis. All patients had greater than 2-year follow-up (average follow-up = 25.5 ± 4.8 months) and utilized the same humeral stem (Equinoxe® platform shoulder; Exactech, Inc.). Forty-six patients, 19 females (average age: 65.6 years) and 27 males (average age: 61.4 years) had primary aTSA with the cage glenoid implant. Forty-six age, sex, and follow-up matched patients, 19 female (average age: 64.7 years) and 27 males (average age: 62.2 years), had aTSA with cemented UHMWPE pegged component. These age, sex, diagnosis, and follow-up patients were evaluated and scored preoperatively and at latest postoperative follow-up using SST, UCLA, ASES, Constant, and SPADI scoring metrics. Active range of motion, including forward flexion, abduction, external rotation and internal rotation, was also measured. Internal rotation was also measured by vertebral segment with the following discrete assignment: 0° = 0, hip = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, T12-T8 = 6, and T7 or higher = 7. Average follow-up for aTSA with cage glenoid was 25.3 ± 4.8 months. Average follow-up for aTSA with UHMWPE pegged implant was 25.6 months ± 4.8 months. True anterior-posterior (AP) and axillary lateral radiographs were obtained postoperatively and at scheduled follow-ups, including the 2-year postoperative evaluation. These radiographs were evaluated and graded for the presence of radiolucent lines by the operating surgeon at the bone cement interface according to the method of Lazarus and coworkers (Table 1 and Fig. 2).[18] Statistical analysis was performed using a Student's two-tailed, unpaired t-test to identify differences in preoperative and postoperative results,

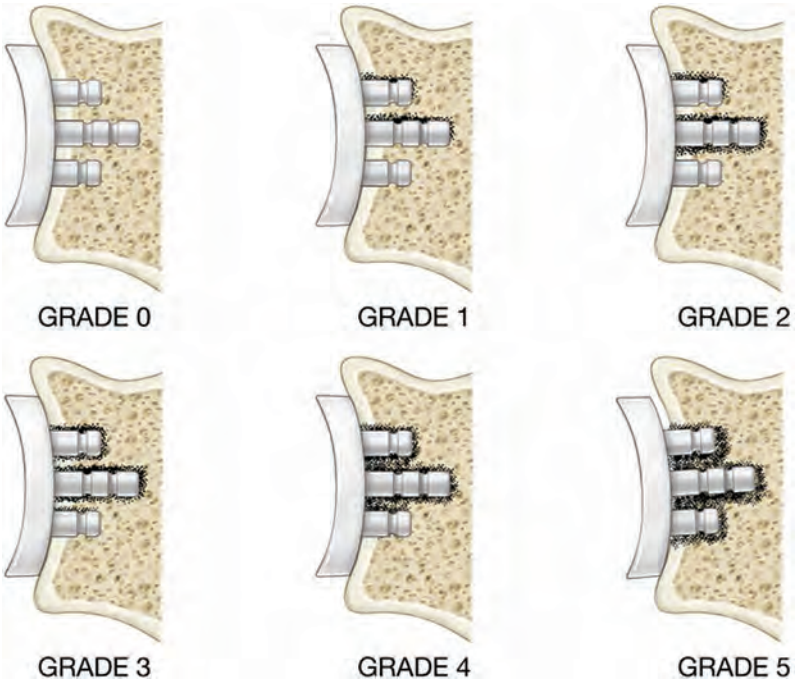

Figure 2 Radiolucent line scoring method. (Adapted from Lazarus MD, Jensen KL, Southworth C, Matsen FA 3rd. The radiographic evaluation of keeled and pegged glenoid component insertion. J Bone Joint Surg Am. 2002 Jul;84A(7):1174-82.)

where $p < 0.05$ denoted a significant difference.

Surgical Technique

The overall surgical technique for the cage glenoid varies little from our standard aTSA arthroplasty technique and has been described previously.[19] The primary distinction of the cage glenoid technique is that it requires "straight line" glenoid insertion. Unlike a standard all-polyethylene implant in which the prosthesis can be rolled into the glenoid, the caged implant must be inserted directly perpendicular to the face of the glenoid from the time the central peg engages the drilled glenoid bone until it is fully seated after impaction. This step is aided with the Spider inserter/impactor (Fig. 3). This straight-line impaction requires excellent glenoid exposure, and caution should be carried out in patients with difficult exposure or significant glenoid deformity.

Glenoid preparation is identical for the all-polyethylene peg glenoid and the cage glenoid, as each of the four pegs are positioned identically so that the surgeon can freely switch between implants (depending upon bone quality and

exposure) after the surface has been reamed and the peg holes have been drilled. Two orthogonal lines are drawn, dividing the anterior-posterior and superior-inferior halves of the glenoid face. The proper position of the central peg hole is consistently just anterior and superior to the intersection of these two lines. The position is confirmed with the glenoid drill guide. The central hole can be drilled either through the guide or in a freehand method. Sequential reaming is carried out to the appropriate size. After trialing, the option of either an all-polyethylene glenoid or cage glenoid component still exists. If straight-line insertion is possible and bone density is adequate, a cage glenoid component is selected; however, if straight-line insertion is not possible, either further releases are performed, or the all-polyethylene pegged glenoid is selected.

The glenoid is prepared in the standard fashion for cementation. The peripheral holes are irrigated free of blood and debris, and cement is pressurized into only the peripheral holes. Straight-line insertion is paramount, as off-axis and eccentric impaction may lead to damage to the locking mechanism that fixes the pegs to the glenoid component. After impaction, care should be taken to assess full seating of the entire glenoid, particularly posterior.

Results

All patients demonstrated a significant improvement in pain and function following treatment with primary aTSA using either glenoid component. A few differences were noted between the cohorts. Table 2 shows that mean active abduction was greater preoperatively for the cage glenoid cohort. Table 3 shows that the mean SPADI score was superior, and the mean active forward flexion measurement was greater for the cage glenoid cohort postoperatively as compared to the all-polyethylene peg glenoid cohort. However, as presented in Table 4, there were no statistically significant differences in the improvement of range of motion or outcome scores for either group. The database contained three complications for the cage glenoid cohort (one infection, one adhesive capsulitis, and one aseptic humeral loosening) and three complications for the all-polyethylene peg glenoid cohort (two infections and one aseptic glenoid loosening).

Radiographic data was available for 37 of 46 (80.0%) cage glenoid patients and 29 of 46 (63.0%) UHMWPE pegged patients. Five of 37 cage glenoid patients had a radiolucent line (13.5%) with an average radiographic line score of 0.22. Eight of 29 UHMWPE pegged glenoids had a radiolucent line (27.6%) with an average radiographic line score average of 0.57. Additionally, average surgical blood loss in patients receiving a cage glenoid aTSA was significantly less than that for patients receiving an UHMWPE peg glenoid aTSA (242 ± 130 ml vs. 337 ± 207 ml, $p = 0.022$).

Discussion

Cemented pegged all-polyethylene glenoid components have been recognized as the current gold standard for aTSA. While clinical results are good with cemented all-polyethylene glenoid components, aseptic loosening remains an unsolved problem and a major cause of long-term failure in aTSA. Previous attempts at uncemented and limited cemented glenoid implants have met with very limited success.[1,4,11] The primary disadvantage of these implants has been the need for metal backing.

The results of this comparison study demonstrate that the novel hybrid cage glenoid has equivalent short-term clinical outcome results and equivalent complication rates as the gold-standard all-polyethylene peg glenoid at 2-year minimum follow-up. Over 5,000 of these devices have been implanted worldwide since 2011, with a very minimal number of reported complaints. Additionally, the cage glenoid implant showed less than half the rate of radiolucent lines (13.5% vs. 27.6%) and less than half the average radiographic line score (0.22 vs. 0.57) than the cemented all-polyethylene peg glenoid implant. Finally, significantly lower blood loss (242 ± 130 vs. 337 ± 207 ml blood loss, $p = 0.022$) was noted in the cage glenoid cohort. This lower blood loss was felt to be related to decreased operative time, owing to the immediate interference fit of the cage peg and not having to wait for cement curing.

This clinical outcome comparison study has some limitations. It presents the short-term clinical results of two different glenoid designs using a database. While incorporating data from multiple sites improves the generalizability of the experience, it also introduces differences in technique and method between sites. Furthermore, there is inherent bias in the operating surgeon scoring their own radiographic results. The rate of radiographic follow-up also needs to improve; while complete radiographs were obtained for 80% of cage glenoid patients, only 63% of all-polyethylene peg glenoid patients had complete radiographic follow-up. Future work should utilize a single or multiple independent evaluators to perform a more complete radiographic analysis between cohorts. Finally, longer-term clinical and radiographic follow-up are needed to determine if these theoretical advantages will result in lower rates of aseptic glenoid loosening and better implant survivorship.

Conclusion

At two-year minimum follow-up, hybrid cage glenoids show equivalent short-term clinical outcomes as all-polyethylene pegged glenoid implants. Furthermore, the cage glenoid implant was demonstrated to have significantly fewer radiolucent lines, and the procedure is associated with significantly lower intraoperative blood loss compared with aTSA with the all-polyethylene peg glenoid. Longer-term clinical follow-up and more intense radiographic scrutiny are required to confirm these results. However, these short-term results are promising and suggest that the hybrid cage glenoid may provide an alternative to gold-standard cemented all-polyethylene peg glenoids, having a potential for a lower risk of aseptic glenoid loosening.

Correlation Between Clinical Outcomes and Anatomic Reconstruction with Anatomic Total Shoulder Arthroplasty

Pierre-Henri Flurin, M.D., Christopher P. Roche, M.S., M.B.A., Thomas W. Wright, M.D., and Joseph D. Zuckerman, M.D.

Abstract

Many glenohumeral studies have demonstrated how anatomy varies across the population. Third and fourth generation shoulder prosthesis designs were developed to provide greater modularity and size ranges to better reproduce this anatomy and thus achieve better results in terms of shoulder function. This study quantifies the quality of anatomic reconstruction and compares that to long-term clinical outcomes using one fourth generation platform shoulder system.

Methodology: One hundred and forty primary total shoulder arthroplasties were performed by one experienced single surgeon between 2001 and 2009, using the same fourth generation modular prosthesis. Pre- and postoperative clinical assessments were quantified with the Constant, ASES, SPADI, SST, and UCLA scores, and active range of motion was measured. Five anatomic parameters were defined, measured, and compared pre- and postoperatively on the anterior-posterior (AP) radiographs: Humeral Head Height (HHH), Humeral Head Centering (HHC), Humeral Head Medial Offset (HHMO), Humeral Head Diameter (HHD), and Humeral Neck Angle (HNA). The differences between each of the parameters were then calculated and rated from 0 to 2 and then summed for each patient to obtain the Anatomic Reconstruction Index (ARI), which objectively quantifies and assesses the quality of the anatomic reconstruction. Patients were sorted based upon their ARI score into two groups (ARI 5 to 7 and ARI 8 to 10), and their latest follow-up outcomes were compared using the Mann-Whitney test to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significant difference.

Results: Of the 140 primary prostheses performed, 78 patients were lost to follow-up, and 13 were excluded for complications that were not related to the anatomic reconstruction. Forty-nine patients (75.8 yrs., 31F/18M) were included with an average follow-up of 9.1 years. The average score for HHH was 1.9 ± 0.4, 1.8 ± 0.5 for HHC, 1.7 ± 0.5 for HHMO, 1.7 ± 0.5 for HHD, and 1.5 ± 0.7 for HNA. Thus, all reconstructions were rated good to excellent with 86% of very good/excellent reconstruction (ARI 8 to 10) and 14% good reconstruction (ARI 5 to 7). A comparison of radiographic anatomic parameters was performed for these two cohorts: HHC (< 0.0001), HNA (0.000), and ARI (<0.0001) were significantly greater for the ARI 8 to 10 cohort. Four of five postoperative clinical outcome metrics for the ARI 8 to 10 cohort were significantly greater than the mean values for the ARI 5 to 7 cohort. Additionally, mean postoperative pain on a daily basis and shoulder function for the ARI 8 to 10 cohort were significantly greater than that for the ARI 5 to 7 cohort.

Discussion: The relatively small number of good reconstructions (14%) compared to very good/excellent reconstructions (86%) and the absence of fair/poor reconstructions limited the ability for any strong linear correlations between anatomical reconstruction and clinical parameters. Despite this, patients with larger mean ARI scores were associated with significantly better outcomes for some measures. This study is limited by the use of 2D assessments from standard AP radiographs; this method can be further refined by the use of 3D quantitative assessment of each parameter.

Conclusion: This study confirmed that an improved anatomic reconstruction results in better postoperative clinical

outcomes. The fourth generation prosthesis used for this study allows continuous in-situ adjustment of the humeral head orientation through use of the spherical taper on the replicator plate and also a double adjustment of offset through the use of the offset humeral head and offset taper on the replicator plate.

Charles Neer determined that a shoulder prosthesis that would reproduce, as closely as possible, the natural anatomy should provide the best clinical outcomes. Despite the results published in 1955 showing a significant improvement in shoulder function, the first-generation prostheses failed to fully achieve this objective, mainly because of the limited size of implants available and their inability to account for the range and variability of proximal humeral anatomy.[1,2]

From the 1970s, the second generation of shoulder prostheses developed around the concept of modularity, which moved closer to the vision of Neer to create a more anatomical reconstruction. Their results were marked by difficulties resulting from two main factors: malposition of the center of rotation and oversizing the humeral head; both of which negatively influenced rotator cuff function and glenoid fixation, a limiting factor in the life of total shoulder arthroplasty.[3,4]

Many studies have analyzed the morphology of the shoulder and demonstrated how its anatomy varies across the population. In light of this information, third and fourth generation shoulder prosthesis designs were developed to provide greater modularity and size ranges to better reproduce the anatomy with even more precision and thus achieve better results in terms of shoulder function and longevity of prosthetic implants.[3,5-13]

Our first anatomic correlation study conducted in 2004 on a series of 50 fourth generation Equinoxe® prostheses with a mean follow-up of 23.8 months compared the quality of anatomic reconstruction on short-term clinical outcomes. Analysis of preoperative and postoperative x-rays were used to develop an anatomical reconstruction index and revealed strong correlations between the quality of the reconstruction and clinical outcomes. This study builds upon the prior study by evaluating the quality of anatomic reconstruction on longer-term clinical outcomes.[14]

Methodology

One hundred and forty primary total shoulder arthroplasties for treatment of osteoarthritis were performed by one experienced single surgeon (PHF) between 2001 and 2009. The same fourth generation modular prosthesis has been used in all patients, the Equinoxe® Platform Shoulder System (Exactech, Inc., Gainesville, FL). Humeral anatomical reconstruction was based on the use of a replicator plate and an eccentric modular head able to adjust four independent variables to reproduce the patient humeral anatomy in situ. This device allows independent adjustability of retroversion, neck angle inclination, medial and posterior offset[5] (Fig. 1).

All arthroplasties were performed in all patients through the deltopectoral approach with a subscapularis tenotomy, an anatomical cut, and a tendon-to-tendon repair. Forty-eight prostheses were uncemented (34%). All patients were immobilized in a sling for 3 weeks and followed the same protocol of rehabilitation starting immediately after surgery,

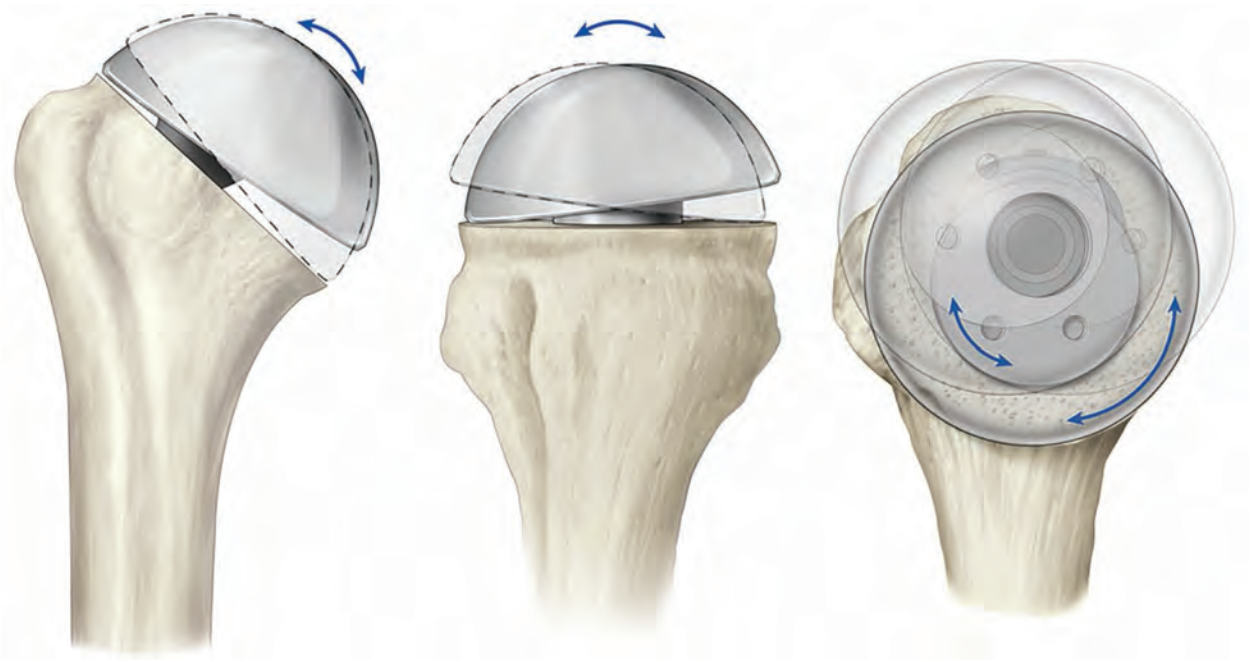

Figure 1 Angular and positional variability achieved with the Equinoxe® shoulder prosthesis. Left image: ± 7.5° humeral neck angle (125° to 140°); middle image: ± 7.5° retroversion modification; right image: ± 6 mm in offset along the plane of the humeral cut.

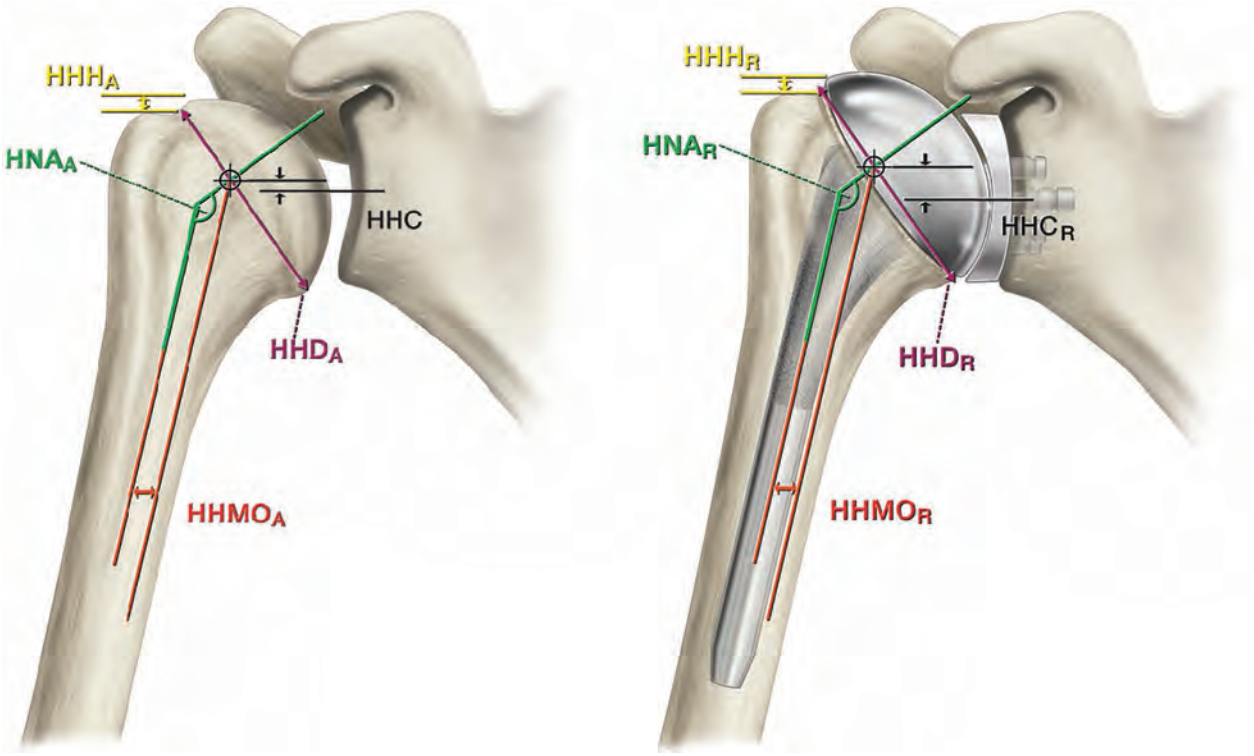

Figure 2 Anatomic reconstruction parameters, left: anatomic shoulder; right: shoulder arthroplasty.

including auto-rehabilitation exercises to be performed three times a day at home, as well as physiotherapist supervised exercises for a minimum of 3 months.

Clinical evaluation and radiographic analysis were performed preoperatively and at the last follow-up. Active range of motion, which included abduction, forward elevation, external, and internal rotation, were measured, and internal rotation was scored as follows: 0° = 0, hip = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, T12-T8 = 6, and T7 or higher = 7. Clinical assessment was based on the Constant, ASES, SPADI, SST, and UCLA scores.[15-19] Constant's best score is 100 points determined by 23 questions to evaluate Pain (15%), Daily Activities (20%), Range of Motion (40%), and Strength (25%). ASES best score is 100 points determined by 11 questions to evaluate Pain (50%) and Daily activities (50%); SPADI's best score is 0 points determined by 13 questions to evaluate Pain (40%) and Daily activities (60%); SST's best score is 12 points determined by 12 "Yes/No" questions to measure patient's ability to carry out activities of daily living. UCLA's best score is 35 points determined by 5 questions to evaluate Pain (29%), Satisfaction (14%), Daily activities (29%), Strength (14%), and Elevation (14%).

As described in Figure 2, five anatomic parameters were selected to define the anatomy of the proximal humerus for the anterior-posterior (AP) radiographic evaluation:

1. Humeral Head Height (HHH, relative to the greater tuberosity);
2. Humeral Head Centering (HHC, relative to the glenoid);
3. Humeral Head Medial Offset (HHMO), distance from the center of the humeral head to the intramedullary axis in the anterior/posterior plane);
4. Humeral Head Diameter (HHD, along the anatomic neck); and
5. Humeral Neck Angle (HNA, angle between the humeral head and intramedullary axis in the anterior/posterior plane).

Table 1 Quantitative Methodology for Rating the Degree of Anatomic Reconstruction from AP Radiographs

	Rating of 0	Rating of 1	Rating of 2
HHH	Pre- and post difference > 6 mm	Pre- and post difference > 3 mm and < 6 mm	Pre- and post difference < 3 mm
HHC	> 25% elevation of the humeral head	< 25% elevation of the humeral head	Head perfectly centered
HHMO	Pre- and post difference > 6 mm	Pre- and post difference > 3 mm and < 6 mm	Pre- and post difference < 3 mm
HHD	Pre- and post difference > 6 mm	Pre- and post difference > 3 mm and < 6 mm	Pre- and post difference < 3 mm
HNA	Pre- and post difference > 8°	Pre- and post difference > 4° and < 8°	Pre- and post difference < 4°
ARI	ARI = HHH + HHC + HHMO + HHD + HNA		

These radiographic parameters were measured on preoperative AP radiographs to define a reference corresponding to the anatomy of each patient. The measurements were then performed on postoperative AP radiographs to characterize the prosthetic reconstruction. The differences between each of the parameters were then calculated for each patient. This difference was then rated from 0 to 2 for each parameter, depending on the scale described in Table 1. The five parametric scores were summed for each patient to obtain the Anatomic Reconstruction Index (ARI), which objectively quantifies and assesses the quality of the anatomic reconstruction.

After collecting the clinical outcome and radiographic data, a statistical analysis was performed with Minitab (Minitab, Inc.) to compare the mean results of the anatomic reconstruction and the clinical outcome scores and ROM data. Given the very high percentage of anatomic reconstruction scores, two subgroups were defined gathering the scores from 5 to 7 and from 8 to 10 (as no scores of 0 to 4 were identified). An Anderson-Darling test for normality was performed on all the data, finding non-parametric distribution. For this reason, subsequent statistical analyses were performed using non-parametric tests. A Mann-Whitney test was used to identify differences in preoperative and postoperative results for each of the ARI cohorts (ARI: 5 to 7 vs. ARI: 8 to 10), where $p < 0.05$ denoted a significant difference.

Results

Of the 140 primary prostheses for osteoarthritis in this evaluation period, 78 patients were lost to follow-up, deceased or unable to come back for this long-term evaluation. Thirteen were excluded of the anatomic correlations study for complications (9%) that were not related to the anatomic reconstruction. Four rotator cuff tears occurred after a very good clinical result from 4 to 9 years at the age of 68, 76, 77, and 77 years old, with a glenoid loosening in three cases. One posterior dislocation also occurred. Four revisions have been done for infection. Finally, we also excluded two subjects with frozen shoulders and two with chronic cervical pain influencing the clinical evaluation without any significant problem with the operated shoulder. Thus, 49 patients were able to be included in this anatomic and outcomes correlation study with a complete clinical and radiographic evaluation with an average follow-up of 9.1 years (range: 6 to 14 years). The mean age was 75.8 years (range: 51 to 95 years), with 63% females (N = 31) and 37% males (N = 18). Table 2 describes the mean preoperative, postoperative, and preoperative to postoperative results for all patients.

The ARI score ranged from 5 to 10 (mean 8.7 ± 1.2) with 1 ARI = 5, 2 ARI = 6, 3 ARI = 7, 12 ARI = 8, 19 ARI = 9, and 12 ARI = 10. The average score for HHH was 1.9 ± 0.4, 1.8 ± 0.5 for HHC, 1.7 ± 0.5 for HHMO, 1.7 ± 0.5 for HHD, and 1.5 ± 0.7 for HNA. Based upon these scores, all reconstructions were rated good to excellent without any bad anatomic results. A very good/excellent anatomic reconstruction (ARI

8 to 10) was observed in 86% of the shoulders and a good anatomic reconstruction (ARI 5 to 7) in 14%. No ARI less than 5 was observed. Complete anatomic restoration (e.g., grade of 2) for each parameter was reproduced in 87.8 % for HHH, 87.8 % for HHC, 71.4 % for HHMO, 75.5 % for HHD, and 69.4% for HNA.

Table 3 presents a comparison of preoperative clinical outcomes for these two cohorts (ARI 5 to 7 versus ARI 8 to 10). As depicted in Table 3, no statistically significant difference in preoperative clinical outcome metric score or range of motion measurement occurred between cohorts. Table 4 presents a comparison of postoperative clinical outcomes for these two cohorts (ARI 5 to 7 versus ARI 8 to 10). As depicted in Table 4, 4 of 5 postoperative clinical outcome metrics for the ARI 8 to 10 cohort were significantly greater than the mean values for the ARI 5 to 7 cohort. Additionally, mean postoperative pain on a daily basis and shoulder function for the ARI 8 to 10 cohort were significantly better than that for the ARI 5 to 7 cohort.

Table 5 presents a comparison of radiographic anatomic parameters for these two cohorts (ARI 5 to 7 versus ARI 8 to 10). As presented in Table 5, HHC (< 0.0001), HNA (0.008), and ARI (< 0.0001) were significantly greater for the ARI 8 to 10 cohort. It should be noted that both the HHC and HNA parameters are not directly dependent upon the prosthesis itself but instead are dependent on the rotator cuff function and also the quality of the surgical osteotomy (Table 4). Linear correlations were performed between each anatomic radiographic parameter and each clinical outcome metric score and each range of motion measurement; however, no parameter was observed to have a strong linear correlation.

Discussion

The results of this study demonstrate the capacity of a fourth generation shoulder prosthesis to reproduce the anatomy of the proximal humerus, which may vary a lot from one patient to the other.[20] Despite this anatomic variation, an average anatomic reconstruction of 8.7 out of 10 was achieved in the patients evaluated in this study. Furthermore, these results demonstrate that patients with very good to excellent anatomic reconstructions (as measured by an ARI of 8 to 10) were associated with significantly better postoperative outcome scores at long-term follow-up (average of 9.1 years).

The relatively small number of good reconstruction (14% had 5 to 7 ARI scores) compared to very good/excellent reconstructions (86% had 8 to 10 ARI scores) and the absence of fair to poor reconstructions (scores < 5) limited the ability for any strong linear correlations between anatomical reconstruction and clinical parameters. The parameter that showed the highest linear correlation with both clinical evaluation scores and range of motion was the HHC. This result is consistent with the study of Nyffeler,[7] who concluded that positioning of the humeral head had consequences in limitation of range of motion and strength. Terrier and coworkers[9] confirmed, with their numerical study, that the position of the humeral head in relation to the glenoid was important

Table 5 Comparison of Anatomic Reconstruction Parameters, Patients with ARI of 5 to 7 Versus 8 to 10

	Humeral Head Height Score	Centering of Humeral Head	Medial Humeral Head Offset	Humeral Head Diameter	Humeral Head Neck Angle	Anatomic Reconstruction Index
Index 5-7 Avg ± St Dev	1.7 ± 0.8	1.2 ± 0.8	1.3 ± 0.8	1.7 ± 0.5	0.5 ± 0.8	6.3 ± 0.8
Index 8-10 Avg ± St Dev	1.9 ± 0.3	1.9 ± 0.3	1.7 ± 0.4	1.7 ± 0.5	1.7 ± 0.6	9.0 ± 0.8
Mann-Whitney P-value	0.6484	**< 0.0001**	0.1565	0.6388	**0.0008**	**< 0.0001**

in restoring mobility and minimizing the risk of loosening.

Clinical parameters, such as pain and shoulder function, were related to the quality of reconstruction, but it was not possible to clearly highlight the correlation with strength and mobility even though the average measures of strength and elevation trended better in the 8 to 10 ARI cohort. This observation may be related to the small number of patients in the ARI 5 to 8 cohort, but it corresponds to the precepts of Neer, constantly confirmed in the literature thereafter, that the quality of clinical results and specifically strength and active mobility depend on the status of the rotator cuff. Although having excluded secondary cuff tears from our study, the function of the rotator cuff deteriorating over time can influence the results of a study like this with an average follow-up of 9 years.

This study has some limitations. One single surgeon performed every procedure and scored the results; while this increases the uniformity of the data and method, it may also limit the generalizability of the results. Future work should incorporate a larger database to include multiple surgeons and multiple sites using the same prosthesis to confirm these conclusions. Additionally, this study is limited by the use of 2D assessments from standard AP radiographs. This method can be further refined by the use of 3D quantitative assessment of each parameter, including continuous measurements rather than discrete categories to improve precision. To this end, future work should incorporate the use of 3D CT reconstructions instead of AP radiographs. In their 3D analysis cadaveric study of 65 shoulders, Walch and Boileau[10] concluded that third generation anatomic prosthesis, by allowing a correct reconstruction of the joint, better restored normal glenohumeral anatomy and kinematics. Other limitations include the lack of independent review in the radiographic scoring.

Conclusion

This study confirmed Neer's concept by demonstrating that an improved anatomic reconstruction results in better postoperative clinical outcomes as measured by 4 of the 5 clinical metrics. The fourth generation prosthesis used for this study allows continuous in-situ adjustment of the humeral head orientation through use of the spherical taper on the replicator plate and also a double adjustment of offset through the use of the offset humeral head and offset taper on the replicator plate. The quality of implantation and the status of the rotator cuff in an aging population may influence the results, which reinforces the need for sharing experience and specialized training for indications and implantations of anatomical total shoulder prostheses.

Effects of Body Mass Index on Outcomes in Total Shoulder Arthroplasty

Elaine Mau, M.Sc., M.D., F.R.C.S.C., Christopher P. Roche, M.S., M.B.A., and Joseph D. Zuckerman, M.D.

Abstract

Body Mass Index (BMI) is one of the metrics used to assess overall health and has been implicated in having predictive value in many aspects of health, including outcomes after shoulder replacement surgery. Outcome data from a multi-institutional database with an average follow-up period of 39.8 months (minimum 24-months) demonstrated that all patients, regardless of BMI, improved significantly after treatment with anatomic total shoulder arthroplasty (aTSA) or reverse total shoulder arthroplasty (rTSA). Improvements in outcomes were stratified and compared based upon BMI in three groups: less than 25, 25 to 35, and greater than 35. Comparing these measures demonstrated that aTSA patients with higher BMI were generally associated with lower functional postoperative outcome metric scores than aTSA patients with lower BMI, though the preoperative to postoperative gains were generally equivalent regardless of BMI. Interestingly, postoperative outcome metric scores with rTSA patients were equivalent regardless of BMI as were the pre-to-postoperative gains. Additionally, differences in the magnitude of pre-to-postoperative improvement of range of motion (ROM) measurements between patients of BMI less than 25 and BMI greater than 35 were noted for forward flexion, internal rotation, and active and passive external rotation. The actual clinical significance of these differences is unknown. Finally, patients with lower BMI appeared to have a higher incidence of low-grade scapular notching.

Over 33% of adults over 60 years of age in the USA were reported to be obese in a national study performed by the CDC in 2011 to 2012.[1] Among this population, many will undergo shoulder replacement surgery for various indications, including osteoarthritis, rheumatoid arthritis, and proximal humerus fracture. National rates of shoulder arthroplasty have markedly increased over the past two decades, with one study finding a two and half fold increase in this procedure between 2000 to 2008.[2] Thus, as obesity has moved to the forefront as a public health issue, questions related to its effects on commonly performed orthopaedic procedures, such as shoulder replacement surgery, have become increasingly important.

The literature on the effects of body mass index (BMI) on outcomes in shoulder arthroplasty has had heterogeneous findings. One recent study of 119 patients reported increased complications after reverse shoulder arthroplasty (rTSA) in patients with BMI less than 25 and BMI greater than 35 when compared against those with BMI 25 to 35.[3] These findings were similar to those reported by Beck and coworkers[4] and Lindberg and associates,[5] whereby obese patients in both studies of 76 and 45 patients, respectively, had significantly more complications than those of normal BMI despite gains in function for both groups postoperatively. Another study of 77 patients undergoing anatomic total shoulder arthroplasty (aTSA) reported no overall physical functional improvements postoperatively as reflected on SF-36 scores for obese patients in comparison to patients with normal BMIs.[6] At the same time, many studies have reported contrary findings, with a lack of evidence supporting the notion that BMI has any negative impacts on outcomes after shoulder arthroplasty surgery.[7-13]

The purpose of our study was to use data gathered from a multi-institutional database to objectively assess the effects of BMI on clinical outcomes with both aTSA and rTSA using a single platform shoulder system.

Materials and Methods

Data acquisition and analysis was performed with approval from the Western Institutional Review Board (IRB), protocol # WIRB 20091701. The data was stripped of all individual subject identifiers and pooled for the following analysis. Preoperative and postoperative data was analyzed from 1,111 patients (69.2 ± 8.8 years) treated by 12 orthopaedic surgeons using either aTSA or rTSA with one platform shoulder system (Equinoxe®, Exactech, Inc., Gainesville, Florida). Four hundred ninety-nine patients received an aTSA (66.0 ± 8.9 years; 265 female, 234 male) for the treatment of degenerative arthritis, and 612 patients received a rTSA (71.8 ± 7.9 years; 389 female, 223 male) for the treatment of rotator cuff arthropathy and osteoarthritis. Each patient was scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI metrics; additionally, active abduction, forward flexion, and active and passive external rotation (ER) with the arm at the side were measured by their surgeons upon follow-up. Internal rotation (IR) was measured by vertebral segments and was scored by the following discrete assignment: 0° = 0, hip = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, T12-T8 = 6, and T7 or higher = 7. Anderson-Darling test for normality was performed on the above data, and found non-parametric distribution of the data. For this reason, subsequent statistical analysis was carried out using non-parametric tests. A Mann-Whitney test was used to identify differences in preoperative, postoperative, and pre-to-postoperative improvements in results for aTSA and rTSA patients sorted into three different BMI groups: less than 25, 25 to 35, and greater 35, where $p < 0.05$ denoted a significant difference.

Characteristics of the comparison groups were as follows: the average follow-up for all patients was 39.8 ± 18.7 months (aTSA: 43.1 ± 21.9 months; rTSA: 37.1 ± 15.1 months). Regarding the aTSA patients, 110 patients had a BMI less than 25 (79 female, 31 male) with an average age of 68.1 ± 9.8 years and an average follow-up of 43.9 ± 21.2 months. Two hundred ninety patients had a BMI greater than 25 and less than 35 (134 female, 156 male) with an average age of 66.0 ± 8.9 years and an average follow-up of 43.4 ± 22.5 months. Ninety-nine patients had a BMI greater than 35 (52 female, 47 male) with an average age = 63.7 ± 7.2 years and an average follow-up of 41.3 ± 21.3 months.

For rTSA patients, 196 patients had a BMI less than 25 (138 female, 58 male) with an average age of 73.5 ± 7.7 years and an average follow-up of 36.4 ± 15.1 months. Three hundred fifty-seven patients had a BMI greater than 25 and less than 35 (217 female, 140 male) with an average age of 71.3 ± 7.7 years and an average follow-up of 37.5 ± 15.3 months. Fifty-nine patients had a BMI greater than 35 (34 female, 25 male) with an average age of 68.9 ± 8.6 years and an average follow-up of 36.2 ± 14.2 months. Among the rTSA group, preoperative and postoperative data was further analyzed in regards to scapular notching. Data from 415 patients (average age: 72.2 ± 7.2 years; range, 50 to 90 years) who received primary rTSA with a minimum of 2-years outcome (average follow-up = 38.1 ± 16.4 months) was examined. Three hundred sixty-three patients (221 female, average: 72.9 years; 132 male, average: 70.6 years) had no scapular notch (age = 72.1 ± 7.2 years), whereas 52 patients (33 female, average: 74.8 years; 19 male, average: 70.6 years) had a scapular notch (age = 73.3 ± 7.6 years). The average follow-up for rTSA patients without a scapular notch was 37.2 ± 16.0 months, and the average follow-up for rTSA patients with a scapular notch was 44.4 ± 17.9 months. Scapular notching was graded using the Nerot-Sirveaux classification system for postoperative notching.[14]

Results

All patients demonstrated overall improvements in range of motion (ROM), pain, and function following treatment with aTSA and rTSA, although to varying degrees. Table 1 presents a comparison of average preoperative measurements between aTSA patients with BMI less than 25, BMI between 25 and 35, and BMI greater than 35. Table 2 presents a comparison of average postoperative measurements between aTSA patients with BMI less than 25, BMI between 25 and 35, and BMI greater than 35. Table 3 presents a comparison of average pre-to-postoperative improvement in measurements between aTSA patients with BMI less than 25, BMI between 25 and 35, and BMI greater than 35. Table 4 presents a comparison of average preoperative measurements between rTSA patients with BMI less than 25, BMI between 25 and 35, and BMI greater than 35. Table 5 presents a comparison of average postoperative measurements between rTSA patients with BMI less than 25, BMI between 25 and 35, and BMI greater than 35. Table 6 presents a comparison of average preoperative to postoperative improvement in measurements between rTSA patients with BMI less than 25, BMI between 25 and 35, and BMI greater than 35.

ROM

For patients undergoing aTSA, two of the five baseline preoperative ROM measurements were significantly worse for patients with greater than 35 BMI than for patients with less than 25 BMI, namely active forward flexion and IR. Postoperatively, three of the five ROM measurements were also significantly worse for patients with greater than 35 BMI than for patients with less than 25 BMI; these were IR, active ER, and passive ER. However, when comparing the mean preoperative to postoperative improvement in measurements between patients with less than 25 BMI and patients with greater than 35 BMI, there were largely no significant differences in the magnitude of improvement between the two groups except for IR and active forward flexion: patients with BMI greater than 35 had significantly less improvement in internal rotation; patients with BMI greater than 35 also had a statistically significantly gain in forward flexion than those with BMI less than 25. When comparing differences in ROM measurements between the BMI 25 to 35 group with the other BMI groups, the BMI less

than 25 group had significantly greater preoperative IR, and the BMI greater than 35 group had significantly less active forward flexion. This was also true of their absolute postoperative IR measurement. However, when improvements in ROM were examined, there was no difference between the BMI less than 25 group and BMI 25 to 35 group in any of the ROM dimensions analyzed. The BMI greater than 35 group had two out of the five ROM scores differ; namely, they had significantly more gains in active forward flexion and significantly less gains in IR compared to the BMI 25 to 35 group; the lack of any significant linear relationship between BMI and ROM was also illustrated with a correlation analysis where r values failed to reach significance for all the ROM dimensions measured across all BMIs.

For rTSA patients, no significant difference was noted in all ROM dimensions measured except for IR, when comparing absolute preoperative ROM or postoperative ROM measurements between those with BMI less than 25 and those with BMI greater than 35. Indeed, IR was the only ROM measurement found to be significantly worse both preoperatively and postoperatively for patients with BMI greater than 35 as compared to patients with BMI less than 25. However, when examining the average improvement in ROM preoperatively versus postoperatively for these two groups, again there were no significant differences in their gains in ROM except for in active forward flexion where the group with BMI less than 25 improved significantly more (average improvement of 59.9 ± 45.7°) than the group with BMI greater than 35 (average improvement of 45.1 ± 43.7°). When data from BMI 25 to 35 group was compared against the other BMI groups undergoing rTSA, although there were few significant differences between the absolute measurements preoperatively (IR for the BMI greater than 35 group was significantly less at their preoperative visits compared to BMI 25 to 35 group) and postoperatively (IR and passive ER for the BMI less than 25 group and IR for the BMI greater than 35 group), there were no significant differences in gains of ROM for most of the five ROM measurements for either the BMI less than 25 or BMI greater than 35 group when compared to the BMI 25 to 35 group at final follow-up, except in active forward flexion for those with BMI greater than 35.

Functional Outcomes Scores

For aTSA patients, all five of the preoperative functional outcome scores were significantly worse for patients with BMI greater than 35 as compared patients with BMI less than 25. Postoperatively, three of the five postoperative functional outcome measurements were significantly lower in patients with BMI greater than 35 than for those with BMI less than 25, namely the ASES, Constant-Murley, and SPADI scores. However, when comparing their mean change in improvement, there were no significant differences in their improved clinical outcome scores between those with BMI less than 25 and those with BMI greater than 35. When comparing the differences in functional outcome scores between the BMI 25 to 35 group against those of the other BMI cohorts undergoing aTSA, it was found that there were no significant differences in preoperative or postoperative scores for those with BMI less than 25; nor were there any significant differences in the average gains in functional scores after surgery for the BMI less than 25 group compared to the group with BMI 25 to 35. However, the group with BMI greater than 35 did have all five preoperative functional measurements differ significantly from those baseline values measured in the BMI 25 to 35 group. Their postoperative functional scores were not significantly different, though, in any of the five ROM categories, and comparison of the average improvement in functional scores only revealed a significant difference in the UCLA score when those with BMI greater than 35 were compared against those with BMI 25 to 35.

For patients undergoing rTSA, those with BMI less than 25 when compared with those with BMI greater than 35 had no significant differences in their absolute preoperative scores, absolute postoperative scores, or in the average improvement in each score from preoperative to postoperative assessment. All five functional scoring methods improved for those BMI less than 25 or those BMI greater than 35, such that there was no significant difference in their scores. When comparing the BMI less than 25 and BMI greater than 35 groups undergoing rTSA with those having BMI between 25 to 35, again there were no differences between their absolute preoperative scores, no significant differences between their absolute postoperative scores, and no significant different findings in their average improvement for each of the five respective functional scores analyzed.

Scapular Notching

In regards to scapular notching, rTSA patients with BMI less than 25, radiographic follow-up was available for 137 patients (70%); 22 patients had a scapular notch (16.1%) and an average scapular notching grade of 0.23. For the rTSA patients with BMI greater than 25 and less than 35, radiographic follow-up was available for 241 patients (68%); 28 patients had a scapular notch (11.6%) and an average scapular notching grade of 0.15. For the rTSA patients with BMI greater than 35, radiographic follow-up was available for 34 patients (58%); one patient had a scapular notch (2.9%) and an average scapular notching grade of 0.03.

Discussion

The results of this study demonstrate that all patients, regardless of BMI, improved significantly after treatment with an aTSA or rTSA. A comparison of outcome measures demonstrated that aTSA patients with higher BMI were generally associated with lower functional postoperative outcome metric scores than aTSA patients with lower BMI, though the preoperative to postoperative gains were generally equivalent regardless of BMI. Interestingly, absolute postoperative outcome metric scores with rTSA patients were equivalent regardless of BMI as were the preoperative to postoperative gains.

This data supports the notion that patients with any BMI can benefit from a total shoulder replacement and achieve significant gains in ROM, pain, and function. This is similar to the findings of Beck and coworkers.[4] While one might postulate that greater restrictions may be imposed by a larger soft tissue envelope, such that uniformly all gains in ROM would be less for those with a greater BMI, our data on average preoperative to postoperative gains in ROM did not support this hypothesis for either aTSA or rTSA. For aTSA, while there were smaller gains in IR after surgery for the patients with increasing BMI groups, there were also greater gains in active forward flexion with increasing BMI. While the average improvement in IR for those with BMI less than 25 is 2.4 ± 1.9 versus 1.7 ± 2.0 for those with BMI greater than 35 is significant; however, whether a 0.7 difference in IR score translates into a clinically important difference despite the statistical difference in these measurements is unclear. Forward flexion similarly was found to be different for patients undergoing aTSA and rTSA, depending on their BMI groups, but it is uncertain whether the absolute difference in improvements will translate into a clinically significant difference. For instance, an average improvement of 49.2° ± 34.8° in active forward flexion was achieved by those with BMI less than 25 undergoing aTSA compared to an average improvement of 52.2° ± 37.9° for those with BMI greater than 35. Yet, some studies in the literature have suggested that a minimum of 11° to 16° in ROM is needed to translate to a clinically important difference given the subjectivity involved with measuring ROM even with a goniometer.[15] Similarly, the absolute magnitude of difference for the few differences in ROM were within this reported minimum range.

Analysis of the functional outcome scores also revealed few significant differences between outcome measure scores for patients of any BMI group, particularly for rTSA in which no differences were observed in any BMI group at any time point. For those undergoing aTSA, only the UCLA was found to have any difference when comparing average improvements between those groups studied and only when comparing patients with BMI between 25 to 35 and those with BMI greater than 35. None of the other functional scores showed any significant differences in their average preoperative to postoperative gains when comparing between groups of varying BMIs. It is notable that among all the outcome measures examined in this study, the UCLA score has been described as being the most poorly characterized measure in validity, reliability, and responsiveness compared to the other measures of outcomes[16] and in this study it was the only measure that was found to be any different between the two groups. Overall, the majority of the findings in this study support the notion that patients of all BMIs can benefit from treatment of either type of shoulder replacement.

A difference in the relative occurrence of scapular notching was noted between the BMI groups, with patients having a lower BMI being associated with a larger scapular notching rate and grade and patients with greater BMI being associated with a smaller scapular notching rate and grade. We suspect that this increased scapular notching rate and grade speaks to both the increased activity level of lower BMI patients but also the increased ROM as patients with thinner arms can achieve greater adduction and bring the arm closer to their torso. This was similar to the findings reported by Falaise and colleagues[17] who also noted that thinner patients had greater adduction of their arms secondary to fewer soft tissue impingements, which in turn was correlated with higher cut angles off the humeral head and subsequently higher glenometaphyseal angles which were found to correlate with greater notching in their studies.

Strengths of the current study design include the multi-institutional nature of the database and the involvement of multiple surgeons, potentially allowing greater generalizability of the results across varying surgical techniques and experience. A variety of scoring instruments were used to assess functional improvement in order to mitigate the shortcoming of any one scoring system. For instance, Roy and associates[18] found that the ASES and SPADI scoring instruments were better than the SST in assessing clinically detectable changes over time, and both the ASES and SPADI have a known minimal quantity that correlates with a clinically important change in the patient (6.4 and 8, respectively), whereas this value is not known for the SST. On the other hand, the SST scoring system was found to have a higher level of reliability, providing more consistency in its results. Also, for both functional outcome scores and ROM, comparisons in improvement were performed, examining the difference in preoperative to postoperative ROM and functional outcome scores rather than comparing absolute scores. This allowed preoperative to serve as an internal control with regard to baseline differences in absolute measurements.

Limitations in study design include the multi-institutional nature of the database study and the lack of independent evaluation at follow-up; surgeons were performing their own assessments at follow-up, potentially leading to a bias for higher ROM scores even in assessments where soft tissue envelopes may obscure accurate measuring. No inter- or intra-observer reliability analyses were carried out. As well, data was collected using a single shoulder system, and thus the ability to generalize to other shoulder system designs may be limited. Furthermore, any differences that may be present during the early recovery phase and how this varies across BMI groups may not be captured in this study given the minimum 2-year follow-up used.

Conclusions

These study results support the notion that the benefits of shoulder arthroplasty appear to extend to patients with a wide range of BMI, given that the other characteristics of patient selection for surgery are satisfied. Although having a BMI in the recommended range may benefit many other aspects of a patient's overall health that would in turn affect their recovery and overall function, this study demonstrates that

those who are classified as obese achieved similar gains in clinical metric scores and ROM as those with lower BMI with both aTSA and rTSA.

Management of Proximal Humerus Fractures with the Equinoxe® Locking Plate System

Kari Broder, B.A., Anthony Christiano, B.A., Joseph D. Zuckerman, M.D., and Kenneth Egol, M.D.

Abstract

There is no consensus on surgical fixation and treatment of proximal humerus fractures, even though they are common fractures with several fixation techniques. This retrospective study quantifies the outcomes of patients who sustained a proximal humerus fracture and were treated with open reduction and internal fixation by at a single academic center between December 2010 and December 2014 using the Equinoxe® proximal humerus locking plate. Following enrollment, injury and surgical data was recorded. Forty-nine patients (31 female, 18 male) with 50 fractures were identified who met the inclusion criteria. Mean follow-up period was 16.8 months (range: 6 to 44 months). Mean age was 60.7 years with no significant difference in mean age by gender. Mean age-adjusted Charlson Comorbidity Index (CCI) was 2.9 (range: 0 to 6). The overall complication rate was 10% (N = 5) with the most common complication being osteonecrosis (N = 3). Four patients required reoperation. At final follow-up, mean active forward flexion for the cohort was 140.8º ± 30.1º, mean passive forward flexion was 155.7º ± 25.2º, and mean active external rotation was 50.1º ± 17.9º. For patients with postoperative complications, mean active forward flexion was 106.0º ± 23.0º, mean passive forward flexion was 136.7º ± 23.1º, and mean active external rotation was 34.2º ± 24.4. Active forward flexion and external rotation were significantly different in the presence of a complication (p = 0.005 and p = 0.038, respectively). Mean DASH score for the cohort was 19.1 ± 20.9. Mean DASH score for patients who developed complications or underwent reoperations was 34.2 ± 24.3. This study demonstrates that the Equinoxe® proximal humerus locking plate provides stable fracture treatment with excellent clinical results and a low complication rate when performed by experienced orthopaedic traumatologists.

Fractures of the proximal humerus comprise approximately 5% of all fractures with between 300,000 to 700,000 reported cases per year.[1-3] These fractures occur commonly as a result of a low energy fall in patients with poor bone quality.[1] Over 70% of proximal humerus injuries occur in patients 60 years and older, overwhelmingly in women over men, with a 3:1 predominance.[4] With our population rapidly aging, orthopaedic surgeons in the USA should anticipate a three-fold increase in proximal humerus fractures within the next 30 years.[4,5] Already, the rate of proximal humerus fracture operative treatment increased by 25.6% from 1999 to 2005.[6,7] These facts underscore the importance of care of proximal humerus fractures, as well as the method of fixation when operative treatment is selected. However, there is still no consensus in the literature concerning the optimal management of these injuries, due to high rates of complications, such as osteonecrosis (ON) and screw penetration and also due to the variety of implants and surgical techniques available that are utilized for fracture fixation.[7-10] Options for treatment include percutaneous pinning, intramedullary nailing, locking plates, hemiarthroplasty, or reverse total shoulder arthroplasty, each offering advantages and disadvantages.[8,11] Locking plates have been a significant improvement in proximal humerus fracture fixation, as they potentially maintain anatomical alignment and stable fixation, especially in osteoporotic bone.[8] While one study has analyzed one company's proximal humerus locking plate, the Proximal Humerus Internal Locking System (PHILOS), there have not been detailed examinations of other implant types.[12] In 2010,

Exactech, Inc., (Gainesville, FL) released the Equinoxe® proximal humerus locking plate with several new improvements on existing locking plate designs. The purpose of this study is to present the patient outcomes and complication rates of 55 consecutive proximal humerus fractures treated with the Equinoxe® proximal humerus locking plate.

Methods

This retrospective study reports on the evaluation of patients who sustained a proximal humerus fractures and were treated by fellowship trained orthopaedic traumatologists at a single academic center between December 2010 and December 2014 using the Equinoxe® proximal humerus locking plate. The institution's Institutional Review Board approved the study. All patients who underwent open reduction and internal fixation (ORIF) with the Equinoxe® locking plate between December 2010 and December 2014 were identified. Exclusion criteria included lack of complete functional data or follow-up less than 6 months. Fractures were classified according to the Neer classification.[13] Surgical intervention was indicated for significantly displaced fractures and based upon the number of anatomic fragments. Surgeons experienced in the technique and implant performed all procedures. All surgeries were performed in the beach chair position. All patients were administered regional anesthesia, general anesthesia, or a combination of the both. The surgeries were performed via a deltopectoral or superolateral approach.

The Equinoxe® proximal humerus locking plate was developed to restore the anatomy of the native shoulder, incorporating contours that correspond to the lateral humerus to increase fit and stability.[14] The fracture plate system was introduced in the USA in 2010 and features a design that attempts to reduce humeral head collapse and improve outcomes for patients with suboptimal bone stock by maximizing contact area. Additional features include the ability to deploy bone filler after plate seating, multiple screw and blade configurations, and a design to allow suture placement after the plate is secured (Fig. 1).

Patients undergoing treatment with the Equinoxe® proximal humerus locking plate were followed at standard intervals using the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire to assess functional outcome and with physical examination and radiographic examination to determine clinical outcome or development of a complication at 3, 6, and 12 months after surgery and as available beyond 12 months.[15] The DASH results in a score between 0 to 100 where 0 = no disability and 100 = extreme disability.[16] Complications were also recorded, if present. Humeral head osteonecrosis (ON), surgical site infection, screw penetration, and heterotopic ossification limiting mobility were considered complications. Descriptive statistics were utilized to identify mean DASH scores, complication rates, and most prevalent complications among the data set. Student's t-test were utilized to determine if DASH scores were statistically significantly related to Neer classification or presence of complication.

Figure 1 The Equinoxe® fracture locking plate with (top) and without (bottom) blade (Exactech, Inc., Gainesville, FL).

Results

A total of 55 consecutive patients underwent proximal humerus repair with the Equinoxe® locking plate during the study period. Five patients were excluded from the study due to inadequate follow-up, and one patient was excluded due to concomitant fractures that affected extremity function. The remaining 49 patients with 50 fractures had a mean follow-up of 16.8 months (range: 6 to 44 months). Of the 49 patients, 31 (63%) were female and 18 (37%) were male, with a mean age of 60.7 ± 14.5 years (range: 25.9 to 87.7 years), with no significant difference in mean age by gender. The mean age-adjusted Charlson Comorbidity Index (CCI) was 2.85 (range: 0 to 6). The fracture classifications were: 19 (38%) two-part fractures, 18 (36%) three-part fractures, and 13 (26%) four-part fractures. The overall complication rate was 10% (N = 5). The most common complication was ON (N = 3; 6.0%) followed by infection, heterotopic ossification, and screw penetration (N = 1; 2.0% each) (Fig. 2). Four patients required reoperation (8.0%). Two patients underwent removal of hardware with irrigation and debridement for infection, one patient underwent removal of hardware for ON and screw penetration, and one patient underwent arthroscopic release for adhesive capsulitis. All patients healed radiographically with the exception of one patient who developed ON and infection and underwent subsequent removal of hardware. At latest follow-up, mean active forward flexion for the cohort was 140.8º ± 30.1º, mean passive forward flexion was 155.7º ± 25.2º, and mean active external rotation was 50.1º ± 17.9º.

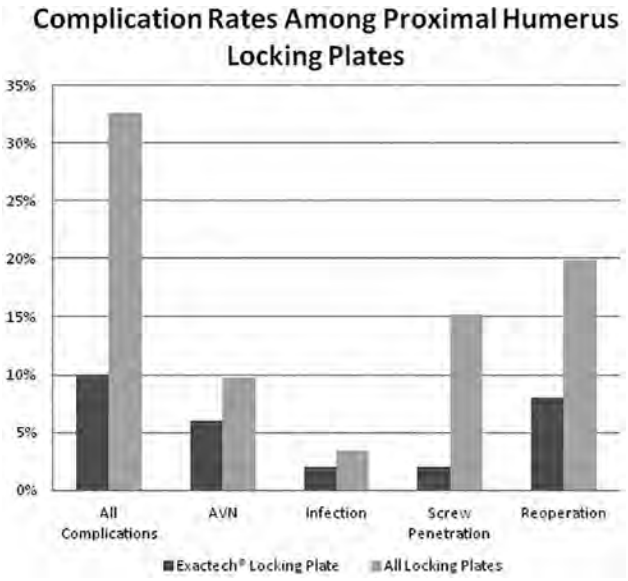

Figure 2 Complication rates for our cohort of Equinoxe® locking plates versus literature-reported rates for all locking plates. Rates for ON, screw penetration, and reoperation were calculated as the averages of ranges put forth by multiple sources.[4,10]

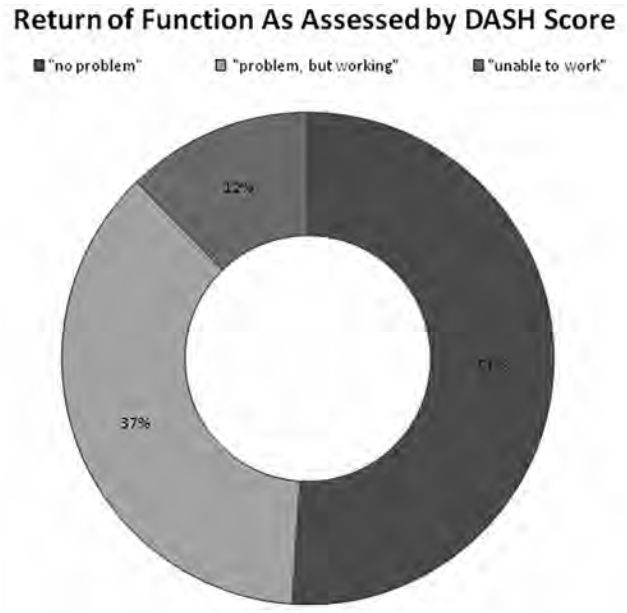

Figure 3 Functional healing as assessed by the DASH score for the patients in our cohort with complications. A DASH score of less than 15 corresponds to "no problem," a score between 15 to 60 "problem but working," and a score of more than 60 "unable to work."[15]

For patients with postoperative complications, mean active forward flexion was 106.0º ± 23.0º, mean passive forward flexion was 136.7º ± 23.1º, and mean active external rotation was 34.2º ± 24.4. Active forward flexion and external rotation were statistically significantly different in the presence of a complication ($p = 0.005$ and $p = 0.038$, respectively). Mean DASH score for the cohort was 19.1 ± 20.9. Mean DASH score for patients who developed complications and or underwent reoperations was 34.2 ± 24.3 (Fig. 3).

Discussion

We found favorable clinical and functional outcomes with use of the Equinoxe® locking plate, with a safety profile comparable to any other plating system available on the market.[10,12] The implant allowed for reliable fracture healing, early range of shoulder motion, and a low complication rate. The mean DASH score reported in this series corresponds to a high level of functionality in patients treated in this series.

Surgical fixation of proximal humerus fractures should offer the opportunity for anatomic restoration, with the potential to meet the patient's expectations of functionality and postoperative shoulder movement. All internal fixation techniques have strengths and weaknesses. Percutaneous pinning and nailing provide a minimally-invasive surgical method but offer less stability than other constructs, leading to high nonunion and malunion rates.[17] While percutaneous pinning may be the least invasive method of operative fixation and therefore provides a theoretically lower chance of osteonecrosis, it carries potential complications of pin migration and osteomyelitis.[6,18] Intramedullary nailing may be useful in osteoporotic bone but has shown to have inferior stability compared to plating and is associated with rotator cuff dysfunction.[18] Maier and coworkers[6] demonstrated that nailing may be utilized for three-part and four-part fractures with either metaphyseal comminution or diaphyseal fracture with only minimal tuberosity displacement. Non-locked plates for proximal humerus fractures have fallen out of favor, especially in poor bone due to screw pullout and implant failure.[5,8]

Locking plates are considered the gold-standard implant for ORIF of the proximal humerus, due to their strength and rotational stability.[2,19] One biomechanical study demonstrated that locking plates were less sensitive than other constructs to bone mineral density in the proximal humerus, making them a better choice for osteoporotic bone. The study also showed that, among intramedullary nail and plate constructs, locking plates offered the greatest stability, under both bending and torsional loading.[20] This combination of strength and stability reduces the risk of failure that accompanies many other implants.[2,20]

The DASH score is considered a reliable and accurate method of ascertaining functionality and disability in the upper extremity.[16] A 2012 study of the PHILOS plate reported a mean DASH score of 36.[12] In a review of all available proximal humerus locking plates currently in use, Sproul and colleagues[10] identified an average DASH for patients of 26.6. By comparison, the patients in the present study had a mean DASH score of 19.1, potentially achieving full functionality in many instances. According to de Kruijf and associates,[21] the highest functional outcome (DASH scores) for geriatric patients with proximal humerus fractures undergoing operative treatment was achieved with the use of a locking plate, followed by intramedullary nail, and hemiarthroplasty.

Proximal humerus fracture ORIF is not without its share of complications. Osteonecrosis is most prevalent among Neer three-part and four-part fractures, with findings of 25% to 30% in percutaneous pinning and 3.1% to 16.4% prevalence in locking plate cohorts.[4,10] ON can develop long after initial trauma and surgery, in some cases after 5 years.[10] Correspondingly, results of ON, such as pain, joint arthritis, and decreased functionality, can take years to manifest, although in such cases ON is not an implant-related complication but rather a result of the fracture itself.[10] Because locking plates do not rely on frictional forces, less soft tissue stripping is required for plate placement. This may be the explanation for lower ON rates seen with locked plates compared to historical series. Usually, intra-articular screw penetration occurs concomitantly with ON, as ON decreases bone quality and facilitates humeral head collapse leading to screw penetration.[5] The prevalence of intra-articular screw penetration ranges from 7.5% to 23%.[4,10] The complication rates with the Equinoxe® plates in our cohort are considerably lower than other locking plates series in the literature.[12] Our ON rate of 6% and screw pullout rate of 2.0% are markedly lower than rates for all locking plates and other methods of fracture repair.[4,10]

This study has some limitations. The cohort described in this study was treated by fellowship-trained traumatologists who had extensive knowledge of the Equinoxe® plate system and extensive surgical experience. It was a retrospective study without a control group. Many cases of ON can occur upwards of 5 years postoperatively. Since the implant has not been in clinical use for 5 years, we may see this reported rate increase with longer follow-up.

Conclusion

While locking plate fixation pitfalls are well documented, including high complication rates and loss of reduction, the Equinoxe® proximal humerus locking plate, as reported in this study, provides excellent short-term clinical results with a low complication rate. Proximal humerus fracture fixation is and will continue to be an important skill in any orthopaedic traumatologist's arsenal; additional and longer-term clinical follow-up is necessary to confirm these positive results.

Conflict of Interest Statement

Rate of Improvement in Clinical Outcomes with Anatomic and Reverse Total Shoulder Arthroplasty

Ryan Simovitch, M.D., Pierre-Henri Flurin, M.D., Yann Marczuk, M.D., Richard Friedman, M.D., F.R.C.S.C., Thomas W. Wright, M.D., Joseph D. Zuckerman, M.D., and Christopher P. Roche, M.S., M.B.A.

Abstract

Introduction: The rate of clinical improvement has never been studied after anatomic (aTSA) and reverse (rTSA) total shoulder arthroplasty. This study quantifies the rate of improvement after aTSA and rTSA using five different scoring metrics for 1,641 patients.

Methods: We evaluated 1,641 (69 ± 9.3 years old) patients treated by 14 orthopaedic surgeons using either aTSA or rTSA with a single platform shoulder system. Seven hundred twenty-nine patients received aTSA, and 912 patients received rTSA. Each patient was scored preoperatively and at various follow-up intervals (2 weeks, 6 weeks, 3 months, 6 months, annually, etc.) with a maximum follow-up time of 139 months using the SST, UCLA, ASES, Constant, and SPADI metrics. In addition, range of motion was measured. The rate of improvement was analyzed using a 40-point moving filter treadline over the entire range of follow-up.

Results: All metrics improved in a majority of patients with less than 5% worsening after 6 months. While gains in motion were present in the majority of patients after aTSA, a higher incidence of patients failed to experience improvement in range of motion after rTSA. Clinical worsening was seen in up to 10% and 20% of the visits for active flexion and abduction and external rotation, respectively. The majority of clinical improvement after aTSA and rTSA was noted in the first 6 months with full improvement noted by 12 to 24 months. During the first 12 months, the rate of improvement associated with rTSA patients was generally 30% larger than that of aTSA patients.

Discussion: The results of this large-scale database analysis demonstrate the reliability of improvements in outcomes and motion achieved with both aTSA and rTSA for various indications. For both aTSA and rTSA, less than 5% of patients reported worsening in each of the five clinical metrics after 6 months postoperative follow-up time. This study is significant because it quantifies how patient outcomes improve with time following treatment with both aTSA and rTSA. These results can be used to establish realistic patient expectations regarding the typical follow-up time required for pain to be reduced and function restored following surgical treatment with a total shoulder prosthesis.

Anatomic total shoulder arthroplasty (aTSA) and reverse total shoulder arthroplasty (rTSA) are the accepted treatments for a variety of degenerative conditions in the shoulder. The incidence of total shoulder arthroplasty has risen dramatically over the last decade based on the National Inpatient Sample database.[1] Clinical improvement after both aTSA and rTSA has been well documented.[2-7] In addition, several long-term studies have evaluated the durability of aTSA and rTSA using time to revision and radiographic decline as end points for failure to determine survivorship.[8-10] While there is ample data in the literature examining clinical outcomes and survivorship for aTSA and rTSA, the rate of clinical improvement following surgery has never been studied or compared.

Multiple clinical outcomes tests specific to the shoulder exist. Each test varies on its emphasis on function, pain, and objective assessment. The most common scores utilized in

Simovitch R, Flurin P-H, Marczuk Y, Friedman R, Wright TW, Zuckerman JD, Roche CP. Rate of improvement in clinical outcomes with anatomic and reverse total shoulder arthroplasty. Bull Hosp Jt Dis. 2015;73(Suppl 1):S111-7.

the USA include the Simple Shoulder Test (SST), University of California, Los Angeles (UCLA), American Shoulder and Elbow Surgeon (ASES), Constant, and Shoulder Pain and Disability Index (SPADI) metrics. The SST is composed of a series of 12 questions that assess function specific to work, sport, and activities of daily living (ADL) with a maximum score of 12. The UCLA metric has five questions that examine pain, range of motion, function, strength, and satisfaction with 60% of the responses subjective in nature; 35 is the maximum score. The ASES score is compiled from a series of 11 questions that reflect pain and function evenly with 100 being the maximum score. The Constant score is calculated from a series of 23 questions, 35% of which are dependent on subjective findings, while 65% depend on objective findings; 100 is the maximum score. The SPADI metric is calculated based on pain and function with 130 being the maximum score, but 0 being the best value. Because each metric emphasizes function, pain, and objective findings differently, there can be variability within and between patients and the type of prosthesis.

A better understanding of the rate of improvement associated with aTSA and rTSA is critical to establish accurate expectations for reduction of pain and restoration of function. The setting of more realistic patient expectations preoperatively will likely lead to greater patient satisfaction postoperatively. In addition, an understanding of the rate of improvement for each prosthesis type may allow surgeons to design different strategies of postoperative care for aTSA and rTSA patients. Furthermore, since studies typically employ a different cadre of metrics to assess outcome, it is imperative to understand how different metrics vary from each other.

The purpose of this study is to quantify the rate of improvement after aTSA and rTSA using five different scoring metrics for 1,641 patients using a single platform shoulder prosthesis. In order to achieve this, each follow-up visit was scored and compared to the prior visit beginning from the preoperative visit to the latest postoperative follow-up visit.

Methods

The study group consisted of 1,641 patients treated by 14 orthopaedic surgeons using either an aTSA or rTSA with a single platform shoulder system (Equinoxe®, Exactech, Inc.; Gainesville, FL). These patients were prospectively enrolled in a multicenter database from November 2001 to April 2015. IRB approval was obtained. Average age was 69 ± 9 years. Maximum follow-up was 139 months. Seven hundred twenty-nine patients received an aTSA, and 912 patients received a rTSA. The average age of the aTSA

group was 65 ± 9 years old while the average age of the rTSA group was 72 ± 8 years old. Fifty two percent (N = 384) of the aTSA patients were females while 48% (N = 345) were males. Sixty-five percent (N = 592) of the rTSA patients were females while 35% were males (N = 320). Preoperative diagnosis was varied and is recorded in Table 1.

Each patient was prospectively evaluated preoperatively and then at regular intervals until their latest follow-up. Follow-up visits were typically at 2 weeks, 6 weeks, 3 months, 6 months, and annually thereafter. However, each patient did not have every time point visit in which case evaluation took place at the next possible time point. In order to be included in this study, each patient had to have at least two separate clinical evaluations (follow-up). Five metrics including SST, UCLA, ASES, Constant, and SPADI were recorded. In addition, active abduction, active forward flexion, and active and passive external rotation with the arm at the side were also measured. The difference between each follow-up value and the corresponding preoperative value was recorded as improvement and noted corresponding to its particular time point. A "negative improvement" value demonstrated clinical worsening while a "positive improvement" value demonstrated clinical improvement. These "improvements" once calculated were normalized to a 100 point scale to allow comparison between each scoring metric. A total of 1,851 postoperative follow-ups were entered into the database for aTSA, and a total of 2,588 postoperative follow-ups were entered into the database for rTSA for a total of 4,439 follow-up reports (Table 2). The rate of improvement was analyzed using a 40-point moving filter treadline over the entire range of follow-up.

Results

Positive improvement and clinical worsening relative to the preoperative value for each metric and range of motion were calculated for each follow-up visit. Based on this data, occurences of clinical worsening relative to follow-up time were recorded and analyzed (Table 3). aTSA and rTSA outcomes with each scoring metric were demonstrated to improve in the majority of patients, where approximately less than 5% of reports experienced worsening in each metric after 6 months of postoperative follow-up.

Similarly, motion was demonstrated to improve in the majority of aTSA patients, where less than 8% of reports worsened after 6 months postoperative follow-up. Conversely, rTSA patients were observed to have a higher percentage of patients without improvement in motion after 6 months postoperative follow-up, where less than 10% of patients had reduced active abduction and forward flexion while less than 20% patients had reduced active external rotation and less than 30% had reduced passive external rotation. There was a progressive reduction in improvement between 48 and 60 months after surgery in both the aTSA and rTSA groups for all range of motion except passive external rotation (Table 3).

Regarding the normalized outcome metrics, the pattern of improvement for each metric was similar for both aTSA and rTSA, with the SST demonstrated to have the largest improvement and the Constant demonstrated to have the

smallest improvement for aTSA (Fig. 1) and rTSA (Fig. 2). The ASES, SPADI, and UCLA scores more closely mirrored each other for both aTSA and rTSA. Differences in improvement for both outcome metrics and motion measurements were observed, with rTSA being associated with a larger magnitude of improvement in the Constant score (Fig. 3)

and active forward flexion (Fig. 4) and aTSA being associated with a larger magnitude of improvement in external rotation (Fig. 5). Regarding the rate of improvement, full improvement was reached between 12 and 24 months for both aTSA and rTSA patients, with the majority of improvement noted in the first 6 months (Fig. 6). Finally, during the first 12 months, the rate of improvement associated with rTSA patients was generally 30% larger than that of aTSA patients as described by the slope of the best fit linear trendlines depicted in Figure 6.

Discussion

The results of this large-scale database analysis demonstrate the reliability of improvements in outcomes and motion achieved with aTSA and rTSA for various indications. Less than 5% of patients reported worsening in each of the five clinical metrics after 6 months postoperative follow-up time. Full improvement was noted by 24 months with the majority of the improvement noted in the first 6 months. Utilizing this information, surgeons can counsel their aTSA and rTSA patients that while the majority of clinical improvement will be experienced in the first 6 months, they may continue to make gains for the first 2 years after surgery. Furthermore, rTSA patients can be expected to make gains at a rate 30% faster than their aTSA counterparts, which may be explained by rTSA patient's demonstrating more profound limitations and symptoms preoperatively.

Although the percentage of patients without improvement in range of motion was relatively low (< 8%) after 6 months of follow-up in the aTSA group, the rTSA group had

a higher percentage of patients without improvement. This was true for abduction and flexion (< 10%) as well as active (< 20%) and passive (< 30%) external rotation. Based on these findings, range of motion appears less predictable after rTSA compared to aTSA. Patients should be made aware of this when considering their surgical options.

There is a relatively high percentage of rTSA patients without improvements at all time points pertaining to active and passive external rotation. Since the percentage of improvement for passive external rotation after rTSA stays relatively constant, the procedure appears to be limiting external rotation due to the biomechanics of the rTSA rather than stiffness. Active external rotation gains may be more limited because passive external rotation is limited, not allowing excursion even with sufficient muscle activation. Alternatively, following rTSA the posterior rotator cuff may not be capable of affecting an ideal moment arm due to a change in tension and line of action.[11,12] All reverse prostheses effectively shorten the resting length of the infraspinatus and teres minor, which contributes to the force generated by a muscle. This may have an impact on the degree of external rotation recovered after rTSA and explain why improvement in active external rotation was more prevalent after aTSA as compared to rTSA.

Despite a steady decline in the percentage of patients without improvement for active flexion and abduction through 48 months after both aTSA and rTSA, both groups then noted a steady rise in the number of patients without improvement from 48 months and beyond. Beyond 60 months, the percentage of patients without improvement for rTSA was twice the rate than that for aTSA. This reflects a significant loss of overhead function because each successive data point in the study was compared to the preoperative state. Perhaps these declining results reflect the general deterioration in function occurring with age, particularly given that the average age of rTSA patients was 7 years older (72 vs. 65 years) than that of aTSA patients in this study. Other possible explanations for this finding in the rTSA group are deltoid fatigue and secondary rotator dysfunction.[13] These findings demonstrate the importance of longer follow-up beyond 5 years.

Since the five clinical scoring metrics were normalized on a 100 point scale, it was possible to make comparisons between metrics. In both prosthesis types, the SST demonstrated the greatest improvement, while the Constant score demonstrated the smallest improvement. It is likely that this difference in magnitude with the Constant score is due to its 25% weight of strength in the calculation, which is often difficult to achieve for this elderly patient population. None of the other five scores emphasizes strength so significantly in the overall calculation of score. Such intrinsic differences in the calculations of each metric score highlight the difficulty in comparing studies that employ different metrics. Conflating two studies that use different metrics may lead to improper conclusions. Conversely, the SPADI, UCLA, and ASES metrics more closely mirrored each other, so studies employing these metrics may be more comparable.

One limitation of this study is the number of data points acquired at the later time points. A majority of the 4,439 follow-up data points were recorded prior to 5 years of follow-up with the minority obtained after 5 years as demonstrated in Table 5. Determining trends after 5 years of follow-up is more difficult because of this limitation in data points. Further follow-up time is required to confirm these results and trends.

This study is significant because it quantifies and compares how patient outcomes improve with time following treatment with both aTSA and rTSA. These results are useful to orthopaedic surgeons and clinical researchers since they can be used to establish realistic patient expectations regarding the typical follow-up time required for pain to be reduced and function restored following surgical treatment.

Conclusion

Outcomes after aTSA and rTSA using a platform system reliably improve with the majority of subjective and objective improvement occurring in the first 6 months following surgery. Despite common scoring metrics maintaining improvement over time, range of motion after aTSA and rTSA appears to decrease in a percentage of patients between the fourth and fifth postoperative year. Following rTSA, both passive and active external rotations demonstrate negative improvement or clinical worsening at a high rate persistently during the immediate postoperative period and continuously through a long follow-up period. This limitation is not seen after aTSA where both passive and active external rotation are rapidly achieved in the first 6 months and maintained through long-term follow-up. An improved understanding of the rate of improvement after total shoulder arthroplasty is important to help counsel patients. The setting of more realistic patient expectations preoperatively can lead to greater patient satisfaction postoperatively.

A Comparison and Correlation of Clinical Outcome Metrics in Anatomic and Reverse Total Shoulder Arthroplasty

Pierre-Henri Flurin, M.D., Christopher P. Roche, M.S., M.B.A., Thomas W. Wright, M.D., Yann Marczuk, M.D., and Joseph D. Zuckerman, M.D.

Abstract

Introduction: Indications for anatomic (aTSA) and reverse (rTSA) total shoulder arthroplasty are well defined and dependent on the function of the rotator cuff; however, indications for rTSA have gradually extended to complex fractures, revisions, and primary arthritis in very elderly patients. The risk of secondary rupture of a weakened or degenerative rotator cuff is difficult to assess and can lead the orthopaedic surgeon to hesitate between aTSA or rTSA. It, therefore, seems appropriate to compare these two types of prostheses in terms of pain, functional, clinical outcome metric scores, and complications, despite suspected differences between populations and the respective diseases.

Methodology: 1,145 patients (69.2 ± 8.9 years) were treated by 12 orthopaedic surgeons in France and in the USA, using either aTSA or rTSA with one platform shoulder system. Five hundred twenty-eight patients received aTSA (66.2 ± 9.0 years; 283 female, 245 male) for treatment of degenerative arthritis, and 617 patients received rTSA (71.8 ± 8.0 years; 392 female, 225 male) for treatment of cuff tear arthroplasty, rotator cuff tear, and osteoarthritis. Each patient was scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI metrics; active range of motion was also measured. The average follow-up for all patients was 39.7 ± 18.7 months (aTSA: 42.7 ± 21.9 months; rTSA: 37.1 ± 15.1 months). Improvements in outcome using each metric score were normalized on a 100 point scale, correlated, and compared. A Student's two-tailed, unpaired t-test was used to identify differences in preoperative, postoperative, and pre-to-postoperative improvements, where $p < 0.05$ denoted a significant difference.

Results: Preoperatively, rTSA patients had significantly lower mean outcome scores and significantly lower mean active range of motion as compared to aTSA patients. Postoperatively, rTSA and aTSA patients showed no significant difference in active forward flexion or in mean outcome scores as measured by four of the five metrics. rTSA patients had significantly lower active abduction, internal rotation, and active and passive external rotation than aTSA patients. However, they had significantly better strength (9.7 vs. 7.3 lbs, $p < 0.0001$). Preoperative to postoperative mean improvements were compared between both cohorts. rTSA patients were associated with significantly larger improvements in outcomes and also had significantly better improvements in active forward flexion and strength. Conversely, aTSA patients had significantly better improvement in active and passive external rotation and active internal rotation. Analysis of complications demonstrated a very similar rate between cohorts, with aTSA patients associated with a slightly lower rate (6.6 vs. 7.3%).

Conclusion: This retrospective analysis of prospectively acquired data from 1,145 patients who received either a primary aTSA or rTSA prosthesis demonstrates that each device provides significant improvements with very similar mean results. In fact, the mean clinical outcomes associated with the reverse shoulder prostheses approach that of the "gold standard" anatomic device for their respective indications. Furthermore, the complication rates in this series are very similar and also favorable relative to the clinical literature. Findings, such as these, may at some point extend the indications of the reverse prosthesis to patients for whom an anatomical prosthesis could lead to a premature deterioration of the result.

Conventionally, indications for anatomic (aTSA) and reverse (rTSA) total shoulder arthroplasty are well defined and dependent on the function of the rotator cuff. The reverse prosthesis was initially defined as a salvage procedure where the use of an anatomic prosthesis was impossible. Indeed, the high complication rates reported in the literature and the lack of data on longevity did not encourage the preferential use of this type of prosthesis. Despite this, indications for rTSA have gradually extended to complex fractures, revisions, and more recently to primary arthritis in very elderly patients.[1-3] The latter indication is based on the risk of secondary rupture of a weakened or degenerative rotator cuff that may compromise medium-term results of aTSA. This risk is difficult to assess and can lead the orthopaedic surgeon to hesitate between use of aTSA or rTSA in a number of patients. It, therefore, seems appropriate to compare these two types of prostheses in terms of pain, functional, clinical outcome metric scores, and complications, despite suspected differences between populations and the respective diseases. To this end, we retrospectively reviewed prospectively acquired data in a multi-institutional IRB approved database to compare preoperative, postoperative, and pre-to-postoperative improvements associated with 1,145 patients who received either aTSA or rTSA in France and in the USA. Outcomes for each prosthesis cohort were scored using five different scoring metrics; each metric was normalized and correlated to facilitate a comparison of scoring systems for each treatment type.

Methodology

A total of 1,145 patients (69.2 ± 8.9 years) were treated by 12 orthopaedic surgeons using either aTSA or rTSA with one platform shoulder system (Equinoxe®, Exactech, Inc.), (Fig. 1). The inclusion criteria were primary total shoulder arthroplasty and a minimum 2-year follow-up where revision surgery was excluded from this series. Five hundred twenty-eight patients (46%) received primary aTSA for treatment of degenerative arthritis. The mean age was 66.2 ± 9.0 years, with 54% females (N = 283) and 46% (N = 245) males. Six hundred seventeen patients (54%) received primary rTSA for treatment of Cuff Tear Arthropathy (CTA), Rotator Cuff Tear (RCT), and Osteoarthritis (OA). The mean age was 71.8 ± 8.0 years with 64% females (N = 392) and 36% males (N = 225).

Each patient was scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI metrics. Additionally, active abduction, forward flexion, and active and passive external rotation with the arm at the side were measured. Internal rotation was also measured by vertebral segments and was scored by the following discrete assignment: 0° = 0, hip = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, T12-T8 = 6, and T7 or

Figure 1 Equinoxe® Platform Shoulder System (Exactech, Inc., Gainesville, FL).

higher = 7. The average follow-up for all patients was 39.7 ± 18.7 months (aTSA: 42.7 ± 21.9 months; rTSA: 37.1 ± 15.1 months). Improvements in outcomes using each metric score were normalized on a 100 points scale, correlated, and compared. A Student's two-tailed, unpaired t-test was used to identify differences in preoperative, postoperative, and pre-to-postoperative improvements, where $p < 0.05$ denoted a significant difference.

Results

Both aTSA and rTSA patients demonstrated significant improvements in each scoring metric, significant increases in strength, motion, and function, and significant decreases in pain following treatment. aTSA and rTSA patients had a similar complication rate, where 35 complications occurred in the aTSA cohort (6.6%) and 45 complications occurred in the rTSA cohort (7.3%). For the aTSA patients, radiographic follow-up was available for 383 patients (73%); 113 patients had a radiolucency around at least one glenoid peg (29.5%) for an average radiolucency score of 0.54. For the rTSA patients, radiographic follow-up was available for 415 patients (67.3%); 52 patients had a scapular notch (12.5%) with an average scapular notching grade of 0.17.

Comparing the aTSA and rTSA cohorts revealed several interesting differences. aTSA patients were significantly younger (age = 66.2 vs. 71.8 years; $p < 0.0001$) and had a significantly larger BMI (BMI = 30.1 vs. 27.9; $p > 0.0001$) than rTSA patients. Table 1 presents the differences in preoperative mean measures between aTSA and rTSA cohorts. Preoperatively, rTSA patients had significantly lower mean outcome scores as measured by four of the five metrics (SST, UCLA, Constant, and ASES) and also had significantly lower mean active forward flexion, active abduction, active external rotation, and strength compared to aTSA patients.

Table 2 presents the differences in postoperative mean measures between aTSA and rTSA cohorts. Postoperatively, rTSA and aTSA patients showed no significant difference in mean outcome scores as measured by four of the five metrics, where only the SST was found to be significantly lower for rTSA patients. No significant difference was found in postoperative active forward flexion between aTSA and rTSA. Postoperatively, rTSA patients had significantly lower active abduction, internal rotation, and active and passive external rotation than aTSA patients. However, rTSA patients had significantly better strength (9.7 vs. 7.3 lbs, $p < 0.0001$).

Table 3 presents the differences in pre-to-postoperative mean improvements between aTSA and rTSA cohorts. rTSA patients were associated with significantly larger improvements in outcomes as measured by four of the five metrics (SST, UCLA, ASES, and Constant) and also had significantly better improvements in active forward flexion and strength. Conversely, aTSA patients had significantly better improvement in active and passive external rotation and also internal rotation as compared to rTSA patients.

Table 4 presents the differences in pre-to-postoperative mean improvements for the normalized clinical metrics between aTSA and rTSA cohorts. Similarly, rTSA patients were associated with significantly larger improvements in outcomes as measured by four of the five normalized metrics (SST, UCLA, ASES, and Constant). Table 5 presents the linear correlation of each normalized metric for both aTSA and rTSA cohorts. The ASES and UCLA metrics were the most highly correlated for measuring outcomes with both aTSA and rTSA. Conversely, the SST and UCLA metrics were the least correlated for measuring outcomes with both aTSA and rTSA.

Discussion

The results of this study found several important and significant differences between the preoperative status of these two different shoulder arthroplasty cohorts. Prior to treatment, aTSA patients are younger, have better preoperative strength due to a functioning rotator cuff, but have less passive motion due to limitations associated with osteoarthritis. Conversely, rTSA patients are older and have decreased strength due to the rotator cuff tear, but also have more variable active range of motion. The differences are consistent with what has been previously reported in the literature for these clearly defined indications between the two prostheses types.[1-21]

Despite this, the postoperative functional results of the two cohorts were similar with no difference in the mean postoperative outcome scores as measured by four of five metrics. While aTSA patients clearly had greater postoperative motion and, in particular, better mobility and improvement in rotation (probably related to the functioning rotator cuff), no observed difference was noted in active elevation between cohorts. In contrast, rTSA patients were demonstrated to have significantly larger improvements in outcomes scores and significantly better improvements in active forward flexion and strength.

These findings from 1,145 patients with a mean follow-up of 39.7 months demonstrated similar postoperative range of motion achieved with both aTSA and rTSA, including additional improvement with rTSA. These results are consistent to those reported in our previous database analysis of 200 patients at a mean follow-up of 31.4 months.[19] Additionally, these findings have also been confirmed by other recent studies.[20,21] Levy and coworkers compared the outcomes of each prosthesis type and concluded that rTSA achieved greater improvements in forward elevation than did aTSA.[20] Additionally, Kiet and colleagues reported similar outcomes and range of motion at 2-year follow-up. [21]

Analysis of strength is also consistent with our previous study[19] and clearly favors the reverse prosthesis in terms of the magnitude of postoperative strength and pre-to-postoperative improvement in strength, especially considering preoperative strength was significantly lower in this population. These favorable results with rTSA may be due to the medialized center of rotation of the prosthesis, which increases the deltoid abductor moment arm relative to the anatomic state to improve deltoid efficiency and reduces the muscle force required to elevate the arm.[13,22,23]

Table 1 Comparison of Average Preoperative Measurements, aTSA Versus rTSA Patients

Table 5 Correlation of Improvement in Outcomes Using Five Clinical Metrics: (aTSA/rTSA)

Correlation (aTSA/rTSA)	ASES	Constant	SPADI	SST
ASES	1.000			
Constant	0.788/0.793	1.000		
SPADI	0.850/0.800	0.711/0.741	1.000	
SST	0.727/0.758	0.694/0.762	0.803/0.801	1.000
UCLA	0.852/0.841	0.789/0.827	0.769/0.690	0.634/0.673

Analysis of complications demonstrated a very similar rate between cohorts, with aTSA patients associated with a slightly lower rate (6.6% vs. 7.3%). The relatively low rate of complications for the reverse prosthesis reported in this large database analysis may be partially explained by the exclusion of surgical revisions but is also likely related to the use of a medial glenoid/lateral humerus prosthesis design that is optimized to minimize scapular notching and maximize range of motion and stability.[22-24] Most remarkable, only six dislocations were reported with this rTSA cohort for an instability rate of 0.97%. The 12.5% rate of scapular notching was also low relative to rates reported with other reverse shoulder prostheses[13-16]; however, this reported incidence is consistent with the results of other radiographic analysis using this same prosthesis.[25-28]

Regarding the analysis of different outcome metrics, the observed differences between metrics reflects the different scoring weights utilized for each metric for pain, function, and strength, and may also imply that each scoring metric has different sensitivities for what defines a "worse" patient and what defines a "good" outcome. Given that there is no standardized scoring system to quantify outcomes with shoulder arthroplasty, the results of this outcome study are significant because they provide the orthopaedic surgeon and clinical researcher with an improved understanding of how five of the most commonly utilized scoring systems relate to one another for both aTSA and rTSA. This study also demonstrated that the ASES and UCLA metrics were the most highly correlated, and the SST and UCLA metrics were the least correlated for both aTSA and rTSA. Future work should attempt to better understand these differences, identify sensitivities, and attempt to create a standardized scoring metric to quantify outcomes with total shoulder arthroplasty.

This study has several limitations. It reports on the short- to mid-term clinical results of a single platform shoulder system for 1,145 patients with 2-years minimum follow-up. These comparative results may change with time; the long-term life of the reverse shoulder prosthesis in particular is unknown. Thus, longer-term follow-up for both aTSA and rTSA is necessary to confirm these results. It should also be noted that database analyses, such as this, contain numerous variables (different patient populations, different surgeons, different surgery centers, different rehabilitation methods, different data collection methods, etc.) that limit their impact. We have done our best to standardize the practices of each data collection site and facilitated the use of standardized data collection forms to quantify outcomes using multiple different scoring metrics. The use of multiple different scoring metrics in particular acts to unify the methodology and also diversify any inherent bias between collection sites. Furthermore, we also regularly audit the data to confirm the quality and completeness of the inputs. Another limitation is that all radiographic analyses were performed by the operating surgeon on their own patients, and complete radiographic follow-up was available in less than 80% of patients; future work should increase the percentage of radiographic follow-up and also incorporate the use of a single or multiple independent reviewers of all radiographs to further minimize bias.

Conclusion

This retrospective analysis of prospectively acquired data from 1,145 patients who received either a primary aTSA or rTSA Equinoxe® prosthesis demonstrates that each device provides significant improvements with very similar mean results. In fact, the mean clinical outcomes associated with the reverse shoulder prostheses approach that of the "gold standard" anatomic device for their respective indications. Furthermore, the complication rates of these prostheses are very similar and also favorable relative to the clinical literature. Findings, such as these, may at some point extend the indications of the reverse prosthesis to patients for whom an anatomical prosthesis could lead to a premature deterioration of the result. Longer-term clinical follow-up continues to

be necessary to confirm these favorable findings using this platform shoulder system.

Reverse Shoulder Arthroplasty Augments for Glenoid Wear

Comparison of Posterior Augments to Superior Augments

Thomas W. Wright, M.D., Christopher P. Roche, M.S., M.B.A., Logan Wright, Pierre-Henri Flurin, M.D., Lynn A. Crosby, M.D., and Joseph D. Zuckerman, M.D.

Abstract

Introduction: Patients who are candidates for a reverse total shoulder arthroplasty (rTSA) may have varying amounts and patterns of glenoid wear. The usual treatment of these deformities has been eccentric reaming or bone grafting. Eccentric reaming often removes a large amount of subchondral bone. Bone grafting is technically more difficult and introduces another mode of failure if the graft does not heal. The purpose of this study is to evaluate patients undergoing a rTSA with concomitant superior or posterior glenoid wear who were treated with a superior augmented baseplate (SAB) or posterior augmented baseplate (PAB) without eccentric reaming or bone grafting.

Materials and Methods: Prospectively obtained data were queried from a multi-institutional IRB-approved database. Preoperative and postoperative data were analyzed from 39 patients who received a primary rTSA with either an 8° PAB or a 10° SAB and a minimum of 2 years follow-up. Twenty-four (10 females and 14 males, aged 72.3 ± 8.2 years) received a primary rTSA shoulder with a PAB. Fifteen patients (4 females and 11 males, aged 71.7 ± 9.2 years) received a primary rTSA shoulder with a SAB. Each patient was scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI metrics. Active abduction, forward flexion, and active and passive external rotation with the arm at the side were also measured. The average follow-up for rTSA patients with a PAB was 25.6 ± 3.1 months, and the average follow-up for rTSA patients with a SAB was 32.5 ± 6.5 months. A Student's two-tailed, unpaired t-test was used to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significant difference.

Results: All patients in both groups demonstrated significant improvements in pain and function following treatment with the reverse shoulder arthroplasty. The PAB rTSA cohort had a scapular notching rate of 6.3%, whereas the SAB rTSA cohort had a scapular notching rate of 14.3%. The PAB outperformed the SAB with the ASES, Constant, and active forward elevation measures.

Discussion: The PAB group outperformed the SAB group with the ASES and Constant outcome scores and forward flexion. The reason for this is unknown; however, it may be due to the posterior augment baseplate itself tensioning the remaining external rotators better than the superior augment, or it may be that the posterior augment group had a better posterior cuff. Both implant groups had no revisions or dislocations and had a low notching rate. It appears that a SAB for superior glenoid wear and a PAB for posterior glenoid wear are viable simple solutions in patients undergoing a rTSA, where each preserves glenoid bone and eliminates the need for glenoid bone grafting.

Eccentric glenoid wear presents a difficult surgical element in patients undergoing shoulder arthroplasty. Surgeons have approached this issue from a number of directions, including eccentric reaming, bone grafting, and the use of reverse total shoulder arthroplasty (rTSA). More recently a simplified approach to this problem has been introduced with the use of rTSA augmented baseplates.

Figure 2 Equinoxe® 10° superior augment baseplate (Exactech, Inc., Gainesville, FL).

Metal augments save bone by minimizing reaming and do not require bone grafts to heal. The purpose of this paper is to evaluate and compare the outcomes of two of these augments, the 8° posterior augment and the 10° superior augment. The superior augment is used primarily with cuff-tear arthropathy, and the associated superior posterior wear pattern associated with that diagnosis. The posterior augment is more commonly used for retroverted or posterior worn glenoids seen with osteoarthritis. The posterior augment has also been used in tight shoulders to make docking of the glenosphere on the baseplate easier.

Materials and Methods

Thirty-nine patients with a rTSA and either a posterior (PAB) or superior (SAB) augment baseplate (Figs. 1 and 2) and a minimum of two-year follow-up (average 28.3 ± 5.7) were identified from a multi-institution, IRB-approved database. These data were obtained prospectively, but the database was queried retrospectively. Twenty-four patients (10 females with an average age of 73.1 and 14 males with an average age of 71.6) received a primary PAB rTSA. Fifteen patients (4 females with an average age of 73.0 and 11 males with an average age of 71.3) received a primary SAB rTSA. No patients with previous revisions were included in the study population. The primary diagnoses resulting in the need for a rTSA were cuff-tear arthropathy, irreparable rotator cuff tear, and osteoarthritis. The outcome measures employed preoperatively and then at 3 months, 6 months, and annually postoperatively include Simple Shoulder Test (SST), University of California Los Angeles (UCLA), American Shoulder and Elbow Surgeons (ASES), Constant, and Shoulder Pain and Disability Index (SPADI) scores. Objective measures obtained at the same intervals included active abduction, active forward flexion, active and passive external rotation with the arm adducted, and internal rotation. Internal rotation was measured by anatomic segment, trochanter = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, T12–T8 = 6, and T7 or higher = 7. Radiographic follow-up was performed at 2 weeks, 3 months, and then annually. Average follow-up for the rTSA PAB patients was 25.6 ± 3.1 months and for the rTSA SAB patients 32.5 ± 6.5 months. Finally, a Student's two tailed, unpaired t-test was used to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significance.

Results

The rTSA PAB patients improved significantly ($p < 0.05$) preoperatively to final follow-up with all the outcome and measured parameters (Table 1). The rTSA SAB patients improved significantly ($p < 0.05$) preoperatively to final follow-up with all outcome and measured parameters except active abduction and all measures having to do with rotation (Table 2). There was no significant difference between the two groups' preoperative states (Table 3). When both groups were compared at final follow-up, the PAB patients significantly outperformed the SAB patients with the ASES, Constant, and active forward flexion measures (Table 4). When the amount of improvement from the preoperative state was analyzed, the PAB patients again outperformed the SAB patients in SST, ASES, Constant, active forward elevation, and strength measures (Table 5). No complications were reported in the database for either group.

Radiographic evaluation was available for 16 of 24 PAB patients (Fig. 3) and revealed a scapular notching rate of 6.3%, whereas the notching rate for 14 of 15 SAB patients (Fig. 4) was 14.3%.

Discussion

Treating the dysmorphic eroded glenoid at the time of shoulder arthroplasty is not easy. Treatment schemes have involved eccentric reaming, bone grafting with an anatomic glenoid component, treatment with rTSA, rTSA with bone graft, and now rTSA baseplate augments.[1] The advantages of eccentric reaming are its simplicity and relative ease, but the price to pay is losing a large amount of the best glenoid bone, the subchondral bone.[2] As the glenoid is medialized with eccentric reaming, it rapidly shrinks, and the best bone is lost. Bone grafting in the setting of the anatomic glenoid is very difficult as the glenoid prosthesis is not designed for bone-graft fixation and compression. For that reason, many investigators recommend rTSA for the difficult glenoid even with an intact rotator cuff, because the rTSA baseplate is better suited for bone grafting.[3-6] However, bone grafting adds an element of complexity, and in revision cases the iliac crest

becomes the autograft site or an allograft must be employed. For the bone-grafted rTSA patient to have a successful result, some or all of the bone graft must incorporate. Therefore, the potential lack of bone-graft incorporation introduces another mode of failure with these difficult shoulders. Metal baseplate augments have the advantage of minimizing anterior reaming with the posterior worn glenoid and inferior reaming with the superior worn glenoid.[7] Subchondral bone preservation allows for better support of the implant and associated screws. With metal augments, the use of bone graft is not necessary, thus, graft incorporation is not an issue.

This study evaluated the viability of metal baseplate augments as a simple solution for the eroded glenoid undergoing rTSA. Based on this short-term clinical study of a minimum of 2-year follow-up, both the posterior and superior augments appear to be effective. When comparing the PAB rTSA to the SAB rTSA, the PAB clearly performs better. However, despite their preoperative measures being the same, the PAB is used more for osteoarthritic wear patterns, whereas the SAB is used more for the rotator-cuff arthropathy group. It is likely that the PAB group has a better posterior cuff even though there were no significant differences in strength or rotation observed preoperatively. The SAB group had longer follow-up and a higher percentage of males, which may have had some influence on outcome. Despite these differences, it is possible that the posterior augment itself is superior to the superior augment as it better tensions the remaining posterior rotator cuff and may allow for better clearance between the humeral implant and the native glenoid with external rotation. Concerning notching, the PAB group also appeared to

perform better, though the SAB group had longer follow-up. With numbers this small, we cautiously speculate that it is possible that the posterior augment diminishes posterior contact of the humeral component with the glenoid, reducing the occurance of scapular notching.

Conclusion

In conclusion, it has been shown in the short-term that both the PAB an SAB are viable solutions for treatment of the eroded glenoid. The application of the metal augment solution is straight-forward, minimizes the destruction of subchondral glenoid bone, and eliminates the necessity for using bone graft. The complication and notching rates are low. Based on this small short-term outcome comparison study, the PAB appears to outperform the SAB; however, the reason for this may be multifactorial and not solely related to the implant.

Bone Grafting the Glenoid Versus Use of Augmented Glenoid Baseplates with Reverse Shoulder Arthroplasty

Richard B. Jones, M.D., Thomas W. Wright, M.D., and Christopher P. Roche, M.S., M.B.A.

Abstract

Background: Large glenoid defects are a difficult reconstructive problem for surgeons performing reverse shoulder arthroplasty (rTSA). Options to address glenoid defects include eccentric reaming, bone grafting, and augmented glenoid baseplates. Augmented glenoid baseplates may provide a simpler, cost-effective, bone-preserving option compared to other techniques. No studies report the use of augmented baseplates to correct glenoid deformity in rTSA relative to the use of glenoid bone graft.

Materials and Methods: We retrospectively reviewed 80 patients that received a primary rTSA and received either a structural bone graft or an augmented glenoid baseplate to address a significant glenoid defect. There were 39 patients in the augmented baseplate cohort and 41 patients in the bone graft cohort. The augmented baseplate cohort contained 24 8° posterior augment implants and 15 10° superior augment baseplates. The bone graft cohort consisted of 36 autograft humeral heads and 5 allograft femoral heads. The average follow-up for rTSA patients with an augmented baseplate was 28.3 ± 5.7 months, and the average follow-up for rTSA patients with glenoid bone graft was 34.1 ± 15.0 months. Each patient was scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI metrics. Range of motion data was obtained as well.

Results: All patients demonstrated significant improvements in pain, ROM, and functional scores following treatment with rTSA using either augmented baseplates or glenoid bone graft to correct glenoid defects. The database contained no complications for the augmented glenoid baseplate cohort, and six complications (14.6%) for the glenoid bone graft cohort (including two glenoid loosenings and graft failures). Additionally, the augmented baseplate cohort showed a lower scapular notching rate of 10% as compared to the bone graft cohort which had a notching rate of 18.5%.

Discussion: The results of this study suggest that either augmented glenoid baseplates or glenoid bone graft can be used to address large glenoid defects during rTSA with significant improvement in outcomes. Augmented glenoid baseplates may achieve a lower complication and scapular notching rate, but additional and longer-term clinical follow-up is required to confirm these results.

Glenoid deficiency is a common occurrence in patients undergoing shoulder arthroplasty. It has been reported that 39% of patients with rotator cuff tear arthropathy (CTA) will have acquired glenoid defects.[1,2] Adverse consequences can occur from implantation of a reverse total shoulder arthroplasty (rTSA) in patients with severely eroded glenoids. Excessive medialization of the implants can lead to muscle shortening and inferomedial impingement causing scapular notching resulting in bone erosion and polyethylene wear.[3-6] Superior tilting of the glenoid baseplate can increase the risk of aseptic loosening, increase shear forces, and decrease the stabilizing compressive forces of the reverse shoulder implant.[7-10] Furthermore, excessive glenoid wear medializes the humerus, which can decrease deltoid wrapping around the greater tuberosity leading to instability as well as cosmetic issues in some patients[5,6] (Fig. 1).

Options to address glenoid bone loss with rTSA include eccentric reaming, bone grafting, and the use of augmented glenoid baseplates. Eccentric reaming is non-ideal as it requires removal of additional glenoid bone and further

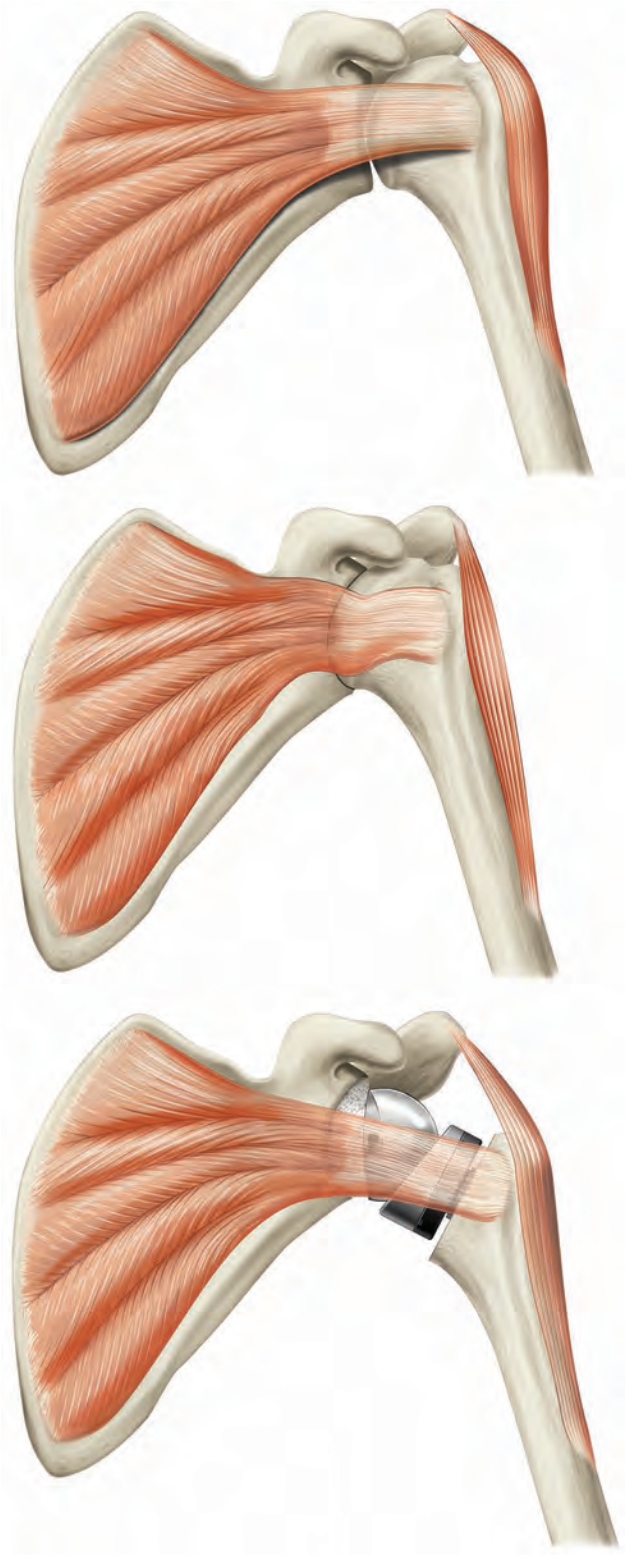

Figure 1 Joint medialization with glenoid wear shortens the rotator cuff muscles and reduces deltoid wrapping. When performing rTSA, bone grafting or augmented baseplates are recommended to restore the native joint line to improve rotator cuff muscle tension and deltoid wrapping.

medializes the joint line.[11-13] The benefits of augmented baseplates include the ability to correct deformity without eccentric reaming, thereby preserving bone stock and avoiding glenoid bone grafting, which adds time and difficulty to the case.[10,14] Glenoid bone grafting also produces greater costs and adds another potential site of failure if the graft does not incorporate.[15-18] The purpose of this study is to compare the outcomes of rTSA in patients with large glenoid defects corrected using either structural bone graft behind the glenoid baseplate or augmented glenoid baseplates. We hypothesized that both options would achieve improved clinical outcomes, and that there would be no difference in outcomes between the two cohorts.

Methodology

An international multicenter data registry was utilized. Preoperative and postoperative data was analyzed from 80 patients with glenoid bone loss (average age: 71.6 years) with a minimum of 2-years follow-up (average follow-up: 31.2 months) and underwent primary rTSA using either an augmented glenoid baseplate (cohort composed of 24 patients with a 8° posterior augment baseplate and 15 patients with a 10° superior augment baseplate) or a glenoid bone graft placed behind the baseplate (cohort composed of 5 patients with allograft and 36 patients with autograft) to obtain glenoid fixation in an eroded scapula. All grafts were used to correct glenoid deficiencies, not to lateralize the center of rotation. Thirty-nine patients (14 female, average age: 73.1 years; 25 male, 71.5 years) received the Equinoxe® rTSA shoulder with an augmented baseplate for treatment of CTA, RCT, or OA with a glenoid defect (average age: 72.1 ± 8.5 years). Forty-one patients (27 female, average: 73.0 years; 14 male, average: 66.9 years) received the Equinoxe® rTSA shoulder with glenoid bone graft for treatment of CTA, RCT, and OA with a glenoid defect (average age: 71.2 ± 7.6 years).

Each patient was scored preoperatively and at latest follow-up using the SST, UCLA, ASES, Constant, and SPADI metrics; additionally, active abduction, forward flexion, and active and passive external rotation with the arm at the side were measured. Internal rotation was also measured by vertebral segments and was scored by the following discrete assignment: 0° = 0, hip = 1, buttocks = 2, sacrum = 3, L5-L4 = 4, L3-L1 = 5, T12-T8 = 6, and T7 or higher = 7. The average follow-up for rTSA patients with an augmented baseplate was 28.3 ± 5.7 months, and the average follow-up for rTSA patients with glenoid bone graft was 34.1 ± 15.0 months. A Student's two-tailed, unpaired t-test was used to identify differences in preoperative and postoperative results, where $p < 0.05$ denoted a significant difference.

Results

All patients demonstrated significant improvements in pain and function following treatment with rTSA using either augmented glenoid baseplates or glenoid bone graft to

correct the glenoid defects (Tables 1 and 2). The database contained 0 complications (0%) for the rTSA patients with an augmented glenoid baseplate and six complications (14.6%) for the rTSA patients with glenoid bone graft (including two glenoid loosenings and graft failures). Radiographic follow-up was available for 30 of 39 augmented baseplate patients (76.9%) and 27 of 41 bone graft patients (65.9%). The augmented baseplate rTSA cohort had a scapular notching rate of 10.0% (all three patients had grade 1 notches); whereas, the glenoid bone graft rTSA cohort had a scapular notching rate of 18.5% (all five patients had grade 1 notches). The average preoperative, postoperative, and pre- to postoperative improvement for each cohort are presented in Tables 3, 4, and 5, respectively. As described in Tables 4 and 5, patients with augmented baseplates and patients with glenoid bone graft were associated with statistically equivalent preoperative, postoperative, and pre- to postoperative improvement in each clinical metric scores and range of motion measurement; the only observed statistical difference between the two cohorts is that the bone graft group was associated with a significantly higher complication rate (0% vs. 14.6%, $p = 0.0126$).

Discussion

The results of this study suggest that either augmented glenoid baseplates or glenoid bone graft can be used to address large glenoid defects during rTSA with significant improvement in outcomes; however, augmented glenoid baseplates were associated with a significantly lower complication and scapular notching rates. Severe glenoid defects that result from bone erosion or trauma sequelae frequently pose a difficult treatment dilemma in patients undergoing shoulder arthroplasty.[19-23] Walch and coworkers developed the most commonly used classification system for glenoid erosion.[24] Type A glenoids have centered humeral heads with either minor (type A1) or major (type A2) glenoid erosion. This was the most common type at 59% in their series. Type B glenoids, the next most common type, consist of posterior subluxation of the humeral head. Type B1 glenoids contain posterior subluxation with no erosion. Type B2 involve posterior erosion with a biconcave glenoid. Type C glenoids involve severe erosion (greater than 25°) and are considered hypoplastic. Building upon this work, Favard and colleagues created a classification system to describe glenoid wear in patients with rotator cuff tear arthropathy.[25] Grade E0 have no wear, E1 have concentric wear, E2 have superior wear, and E3 glenoids have superior and inferior glenoid erosion. Options to address glenoid wear include hemiarthroplasty avoiding the use of a glenoid implant, eccentric reaming, augmented implants, and in cases where more correction is needed, bone grafting. Glenoid bone grafting with shoulder arthroplasty has been described with autograft humeral head, iliac crest, or allograft femoral head.[26-32] Advantages of this technique include maintenance of the joint line and preservation of glenoid bone stock. Disadvantages include technical difficulty, fixation failure, and graft resorption, which could secondarily lead to component loosening.[15-18]

Numerous studies have reported the results of bone grafting with rTSA in the treatment of the deficient glenoid with encouraging short-term outcomes.[33-37] Neyton and associates reported on nine patients who underwent glenoid bone graft with either autograft humeral head or iliac crest combined with rTSA[34]; Constant scores, ROM, and pain scores improved in all patients, and no instances of radiographic loosening occurred at 2-year follow-up. Boileau and coworkers described the use of humeral head autograft to improve lateralization of the center of rotation.[35] They used a 7 mm to 10 mm graft and an extended post on the baseplate and reported a 98% incorporation rate with no loosening or revisions at 28 months.[35] These patients did not require glenoid grafting for glenoid defects, however, and may not be comparable to this study. Melis and colleagues evaluated 37 anatomic TSAs requiring revision to rTSA. They reported that 29 of these patients required bone grafts consisting of structural iliac crest or cancellous autograft and 3 allografts.[36] Seventy-six percent of the grafts incorporated at mean follow-up of 47 months with a complication rate of 30% and a 22% re-revision rate. Werner and associates reported on rTSA for long standing anterior shoulder dislocation with severe anterior glenoid bone loss.[37] They evaluated 21 patients, each of whom received a humeral head autograft on the glenoid. At latest follow-up, all patients showed improvement in functional scores; two graft failures occurred, where one of which was thought to be related to the use of a peg that was too short.[37]

Use of augmented glenoid implants may be an attractive alternative to bone grafting significant glenoid defects.[10,14] Several studies have reported on the use of augmented implants in primary anatomic TSA with variable clinical results.[38-40] While additional clinical follow-up is required to demonstrate the clinical viability of these augmented implants, numerous recent biomechanical studies have demonstrated substantial rationale for these devices to preserve glenoid bone, improve stress transmission to increase the potential for long-term fixation, and improve muscle tensioning with total shoulder arthroplasty.[41-44] No studies exist in the literature regarding use of augmented glenoid baseplates clinically in rTSA applications. Roche and coworkers reported on biomechanical test results of a superior augmented glenoid baseplate versus eccentric reaming with a standard baseplate to correct simulated Favard E2 superiorly worn glenoids with rTSA.[10] After cyclic testing, there was no difference in fixation and displacement between the standard baseplate and the superior augmented baseplate, and the superior augmented baseplate was observed to conserve significantly more bone than the standard baseplate with eccentric reaming. It should be noted that this rTSA glenoid test method has been utilized previously to demonstrate that rTSA baseplates with bone graft (using the BIO-RSA technique) had significantly poorer fixation than rTSA glenoid baseplates without bone graft.[45] Posterior augmented glenoids have also been shown to better restore posterior rotator cuff

Figure 2 Equinoxe® baseplates for eroded glenoids, from left to right: 8° posterior augment, 10° superior augment, combined 10° superior/8° posterior augment, and +10 mm extended cage peg baseplates (Exactech, Inc. Gainesville, FL).

muscle tensioning with rTSA than use of rTSA with standard baseplates.[46]

Currently, three types of augmented rTSA baseplates are available: 10° superior augment, 8° posterior augment, and combined 10° superior/8° posterior augment; a +10 mm extended cage baseplate is also available to facilitate bone grafting of medially eroded glenoids (Exactech, Inc., Gainesville, FL) (Fig. 2). To our knowledge, this is the first comparative outcome study presenting clinical results using augmented baseplates versus use of bone graft to correct glenoid deformities with rTSA. In both cohorts, significant improvements were observed in pain, ROM, and outcome metrics at 2-years minimum follow-up. This offering of augmented implants permits the surgeon to address certain glenoid defects while preserving glenoid bone stock without the use of bone graft. The use of prosthetic augments eliminates the technical difficulties commonly encountered when utilizing structural bone graft for large glenoid defects, as evidenced by the significantly different complication rates observed in this study (0% versus 14.6%, $p = 0.0126$). These complications included two patients with aseptic baseplate loosening, two with intraoperative humeral fractures, one infection, and one patient with persistent pain. The augmented baseplate cohort also demonstrated a lower scapular notching rate than the bone graft cohort (10% versus 18.5%); in both groups, only grade 1 notching was observed. Perhaps these differences result from the increased technical difficulty of fashioning the bone grafts and properly placing the standard implants, potentially leading to less than optimum implant positioning with resultant scapular notching. Other potential benefits of augmented glenoid baseplates include lower surgical costs, shorter operating time, and less patient morbidity by avoiding the use of allografts, fashioning grafts, or at times, harvesting iliac crest autografts.

This study has several limitations. Data was collected from a multi-center database with multiple surgeons rather than just one surgeon and site. This study structure introduces some possible inconsistencies. First, we are unable to determine what criteria each surgeon used to determine when to use an augmented implant versus a bone graft. Many of the bone grafts were used prior to the availability of augmented baseplates, however, leading us to believe the criteria were similar for each group. Furthermore the database does not contain data indicating if preoperative CT scans were used in all cases to determine the amount of deficiency. Nonetheless, each of the six surgeons with cases in this data set were experienced and fellowship-trained; therefore, minimizing the chances that grafts or augments were used inappropriately. Additionally, no differentiation was made between grafts or augments used for eccentric glenoid defects and concentric defects. This comparison may show different outcomes and is an area for future study. Finally, no statistical comparisons are made between the different augmented implant and bone graft sub-groups (e.g., superior augment baseplate or posterior augment baseplates versus allograft or autograft) due to insufficient sample sizes; instead, the graft and augment subgroups were combined. Future work should assess a larger population with longer follow-up. Glenoid defects should be categorized radiographically prior to surgery, and consistent criteria determined for the use of glenoid grafts or augmented baseplates. Isolating each subgroup may elucidate other differences, as different wear patterns and indications may act as confounders and impart various consequences and outcomes after rTSA.

Conclusion

In conclusion, both the use of augmented baseplates and glenoid bone graft to correct significant glenoid wear with rTSA can improve clinical outcomes at 2-years minimum follow-up. In the authors' experience, the use of bone grafts is more technically demanding and leads to higher complication and scapular notching rates compared to using augmented glenoid baseplates with rTSA. Further study is required to elucidate the best treatment option for reconstructing these difficult glenoids when rTSA is the treatment of choice.

Revision Total Shoulder Arthroplasty without Humeral Component Removal

A Preliminary Report on the Role of a Platform Humeral Component

Lynn A. Crosby, M.D., Thomas W. Wright, M.D., and Joseph D. Zuckerman, M.D.

Abstract

Background: Revision total shoulder arthroplasty to a reverse system without removing the humeral component—i.e., a platform system—has been in use since 2006. This preliminary report compares the outcomes of revision total shoulder replacement in patients who underwent revision utilizing a platform system as compared to those patients requiring stem removal.

Methods: The data banks from two academic centers were utilized to review patients who underwent revision total shoulder surgery requiring removal of a well fixed humeral stem and those revised with a well fixed platform humeral stem. All patients underwent revision to reverse total shoulder arthroplasty. Measured variables were pre and postoperative Constant scores, blood loss, operating room time, complications, and cost.

Results: The use of a platform system resulted in fewer complications, less operating room time, and a decrease in blood loss ($p < 0.05$). The Constant scores were not significantly different between the two groups. The cost of implants and operating room time was also less in the platform system group.

Conclusion: Revision total shoulder arthroplasty utilizing a platform system that does not require humeral component removal resulted in a significant decrease in complications, blood loss, and operating room time compared with revisions that did not utilize a platform system. The Constant score was similar between the two groups. The overall cost of the procedure was less when the platform system was used.

Total shoulder arthroplasty (TSA) has consistently demonstrated successful outcomes in terms of pain relief and functional improvement in patients with degenerative conditions of the glenohumeral joint.[1,2] As a result, shoulder arthroplasty procedures have increased dramatically over the past 15 years and are projected to increase by more than 200% between 2010 and 2015.[3] As with any arthroplasty procedure that involves the insertion of prosthetic components, a subset of patients can be expected to require revision for failure. The rate of revision is known to increase as the duration of follow-up increases, particularly with follow-up beyond 5 to 10 years.[2] Long-term outcomes of TSA have shown survival rates of 88 to 97% at 5-year follow-up, 71% to 88% at 10-year follow-up, and less than 50% at 15-year follow-up.[3] Therefore, as the number of primary TSA procedures increase, the number of revision procedures is expected to increase.

There are many possible indications for revision TSA, including aseptic component loosening, malposition of components, infection, instability, and stiffness.[2,4-7] Rotator cuff tears are the most common soft tissue complication following primary TSA, and the rate of occurrence increases with the duration of follow-up.[2] Soft tissue complications including rotator cuff tears are a common indication for conversion from anatomic TSA (aTSA) to a reverse TSA (rTSA), which has been shown to be an effective treatment option for failed TSA by providing stability, reducing pain, and improving function.[4-6,7-9]

Revision TSA can be complex and is typically associated with increased blood loss, prolonged operating room (OR) time, the use of revision implants, and longer hospital length of stay. Frequently revision TSA includes the need for bone

Crosby LA, Wright TW, Zuckerman JD. Revision total shoulder arthroplasty without humeral component removal: a preliminary report on the role of a platform humeral component. Bull Hosp Jt Dis. 2015;73(Suppl 1):S136-9.

grafting procedures (autograft or allograft), cement removal equipment, intraoperative frozen sections, and cultures.[10] Based upon these factors, the cost of these procedures can be expected to be much greater than primary TSA.

A recent design concept utilizes a platform system in which humeral stems are compatible with both anatomic and reverse arthroplasty components. Revision of an aTSA to rTSA with a platform humeral component in place will not require revision of the humeral component if the original stem is well-fixed and in good position.[11] Just as revisions of hemi-arthroplasty to TSA using a modular stem design have been reported to minimize the complexity of the revision procedure, the same advantages can be expected for revision procedures in which a platform humeral stem has been used for the initial procedure. The purpose of this study is to report our preliminary experience with a platform system for revision of an aTSA to rTSA and to compare this experience with a group of patients in which revision of aTSA to rTSA required humeral stem revision. Our hypothesis is that revision of an aTSA to a rTSA with a platform system in place provides advantages in terms of OR time, blood loss, complications, and cost compared with revisions that require humeral component revision.

Material and Methods

To identify the patients for inclusion in this study, we reviewed revision shoulder arthroplasty performed at the following institutions: Medical College of Georgia and the University of Florida Shands Hospital. Patients who underwent revision of aTSA to rTSA were identified. From this cohort of patients, two separate groups of patients were identified:

Group 1: Patients who underwent revision of an aTSA to rTSA and required revision of a non-platform humeral stem. In this group, all patients required removal of the humeral component with insertion of a different humeral component.

Group 2: Patients who underwent revision of an aTSA to rTSA with a platform humeral component in place which did not require humeral stem removal.

A total of 73 patients were identified for inclusion in this study. Group 1 consisted of 45 patients (15 males and 30 females), and Group 2 consisted of 28 patients (11 males and 17 females). Information concerning preoperative characteristics, intraoperative findings, and postoperative follow-up were obtained for each patient. This intraoperative information consisted of blood loss, operating time, and complications; postoperative information included complications and reoperations, two-year outcomes utilizing the Constant score. Costs of implants were obtained from published information. Comparison between the two groups was performed using a Student's t-test with $p < 0.05$ considered significant.

Results

The mean age at the revision surgery was 69 years (range: 57 to 82 years) in Group 1 and 65.8 years (range: 57 to 75 years) in Group 2. For Group 1, the average intraoperative and postoperative blood loss (when drains were used) was 500 cc; for Group 2, it was 280 cc ($p < 0.05$). For Group 1, the mean OR time was 211 minutes (range: 123 to 311 minutes), and for Group 2, it was 145 minutes (range: 115 to 187 minutes) ($p < 0.05$). Most importantly, there was a significant difference in intraoperative and postoperative complications. There were nine complications reported for Group 1, including two infections, one aseptic loosening, two patients with instability, one axillary nerve injury, and three with continued pain of neuropathic origin; for Group 2 there were no intraoperative or postoperative complications ($p < 0.05$). These results are summarized in Table 1.

Table 1 Average Estimated Blood Loss and OR Time and Number of Complications Reported

	Traditional Stem Group 1	Platform Stem Group 2
Blood Loss	500 cc	280 cc
OR Time	211 min (range: 123-311)	145 min (range: 115-187)
Complications	9	0

Group 1 patients also sustained the additional cost associated with replacement of the humeral stem and the additional OR time. In this series, the cost of the revision humeral stem ranged from $3,000 to $8,500.[12] The cost of additional OR time, which averaged 66 minutes between Group 1 and Group 2, reflects an additional cost of over $4,000 based upon published information for cost of operating room time (estimated to be $62.00 per minute)[5] (Table 2).

Comparison of preoperative and postoperative Constant scores did not show significant differences between the two groups. In Group 1, the preoperative and postoperative Constant scores were 20 (12.9 to 27) and 70 (54 to 90), respectively. For Group 2, the Constant scores were 32 (6 to 57) and 75 (60 to 90), respectively.

Discussion

Humeral components used in aTSA and rTSA systems generally reflect distinct differences in design and geometry. As such, revision of an aTSA to rTSA has generally required replacement of the humeral component, even though the humeral component may be well fixed, in good position and generally not indicated for revision.[7,10,13] The challenges

Table 2 Potential Costs Associated with Revision TSA with a Traditional Stem

Cost Type	Estimated Amount
Replacement Stem[12]	$3,000-$8,500
Additional OR time (66 min @ $62/min)[5]	$4,100
Allograft[16]	$500-$1,700
Cables[9]	$800-$1,200

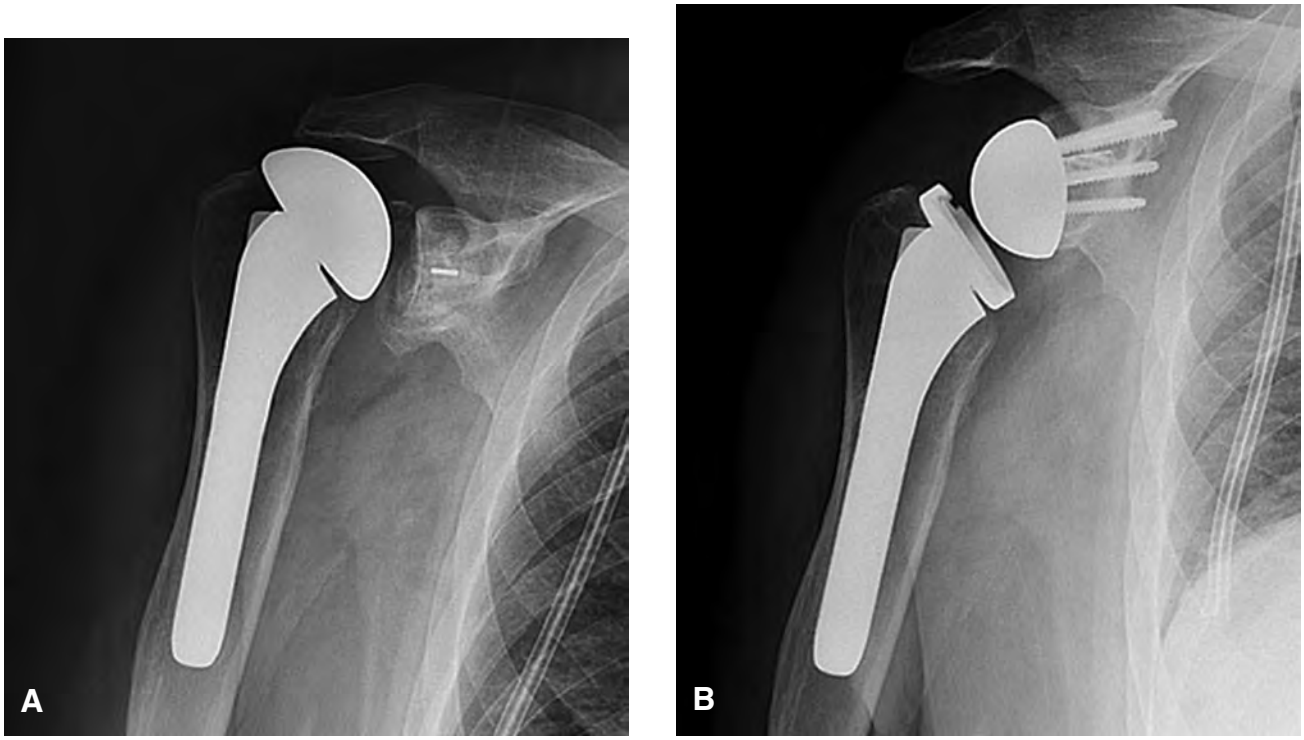

Figure 1 Seventy-two-year-old patient 2 years following a TSA who was involved in a motor vehicle accident. This resulted in a massive rotator cuff tear and instability (**A**). Revision was performed with conversion to a reverse shoulder arthroplasty. Operative time was 120 minutes with an estimated blood loss of 300 cc (**B**).

associated with removing a well fixed humeral stem, particularly for those stems with surface textures that facilitate bone on-growth, can be significant and include excessive bone loss during removal and intraoperative fracture.[10,14] Well-fixed humeral stems may require humeral shaft osteotomy to remove the prosthesis regardless of whether cement fixation is used.[6,7] Therefore, the ability to revise an aTSA to rTSA without the need for removal of the humeral stem could be expected to provide significant advantages and benefits.

In this preliminary report, our comparison of Group 1 and Group 2 clearly showed significant differences between the revision procedures performed for the patients in each group. The patients in Group 2, in which a platform stem was in place and did not require removal at the time of conversion to rTSA showed significantly less estimated blood loss and OR time compared with Group 1. A reduction in the OR time reduces patient risk both by lowering the amount of time under anesthesia and reducing the risk of infection. In addition, complications in Group 2 were significantly less than in Group 1. In addition, the use of a platform stem did not have an adverse impact on outcomes as documented by the Constant score. There was no statistical difference between the preoperative and two-year follow-up Constant scores between the two groups.

Our analysis of the additional costs associated with revision surgery in Group 1 compared with Group 2 requires further discussion. The cost of the humeral implants that were revised for patients in Group 2 ranged from approximately $3,000 to $8,500.[12] The additional OR time, which averaged 66 minutes, is estimated to cost an additional $4,093 when the cost of OR time is $62.00 per minute.[5] We recognize that actual costs may vary based on the individual institution and the specific surgery performed.[15] We utilized cost ranges estimated from current market reports and the available literature.[5,9,12,15,16] A true cost comparison between patients in Group 1 and Group 2 would also include the cost of reoperations, readmissions, professional fees, and the indirect costs associated with time lost from work. We consider this analysis beyond both the scope and the emphasis of this report

When a platform humeral stem is in place, the complexity of a revision procedure when converting aTSA to rTSA can be reduced because revision of the humeral component will often not be necessary (Fig. 1). This provides significant benefits both for the patients as well as the surgeon performing the procedure as documented by reduced blood loss, shorter operative time, fewer complications, and lower costs. This preliminary report supports the hypothesis that TSA systems utilizing a platform stem are beneficial if and when revision to rTSA is necessary. Surgeons should carefully consider the type of humeral stem utilized when performing primary aTSA so that the potential impact on revision surgery is included in the selection of implants.

Infection Prevention in Shoulder Surgery

Daniel J. Hackett, Jr., M.D., and Lynn A. Crosby, M.D.

Abstract

The microbiome of the shoulder demonstrates distinctive differences to other orthopaedic surgical sites. Recent studies have demonstrated that the most common organisms found in deep shoulder infections are coagulase-negative staphylococcal species and Propionibacterium acnes*. Many studies support diligent hand washing, decreasing operative time, routine glove changing, minimizing operating room traffic, and covering instruments as means for decreasing the risk of deep infection. On the other hand, hair clipping and the use of adhesive drapes may have little effect on decreasing the incidence of deep infection. Although generally considered the most efficacious skin preparation solution, chlorhexidine gluconate has minimal effect on eradication of* P. acnes *from the surgical site; however, the addition of preoperative topical applications of benzoyl peroxide to standard surgical preparation has shown promise in decreasing the rate of P*. acnes *culture positivity. Additionally, the use of local antibiotic formulations seems to be an effective means of preventing deep infection.*

Postoperative infections after shoulder surgery are a serious cause of patient morbidity and rising healthcare expenditures. Although the reported rates of infection after shoulder surgery are relatively low, ranging between 0.4% to 5%,[1,2] these infections often require revision surgery, longer hospital stays, and an increased use of antibiotics. Furthermore, these patients often have poorer results than their matched counterparts who have uncomplicated courses.[3] Additionally, with the institution of the Affordable Care Act, postoperative complications, such as infections, may not be reimbursed, placing the burden of caring for infections upon the physician, hospital, or accountable care organization, further necessitating the need for improved infection prevention. Reducing the economic burden of treating postoperative shoulder infections depends on developing clinical practice guidelines, such as those used for hip and knee arthroplasty, and incentivizing innovations in infection prevention.[4] We will examine the current literature regarding infection prevention in shoulder surgery, with special attention directed towards the prevention of *Propionibacterium acnes* infection.

Infective Organisms

As stated previously, the rate of infection after shoulder surgery remains low. The common infective organisms are typically coagulase-negative staphylococcal species, such as *S. epidermidis* and *P. acnes*, both of which are part of the normal skin flora. In a study by Maraceck and colleagues, the skin flora of axilla in male subjects prior to surgical preparation demonstrated the presence of coagulase-negative staphylococcal species and *P. acnes* in 72.9% and 72.4% cultures, respectively. This contrasts to the presence of *Staphylococcus aureus* in only 4.7% of the cultures taken prior to surgical preparation.[5]

P. acnes and coagulase-negative staphylococcal species, such as *S. epidermidis*, are believed to be commensal organisms of the human skin microbiome. These two species help to fight other pathogens, such as *S. aureus*, and maintain homeostasis of the skin microbiome, even maintaining a biologic balance between each other when one species overgrows.[6,7] *P. acnes*, in particular, acts as a chimeric organism. This Gram-positive, saprophytic organism is intimately associated with sebaceous glands. It is an anaerobic organism but is aerotolerant, even expressing the ability to

employ oxidative phosphorylation for energy conservation. It is present throughout the body, notably the gut, where, just as it does on the skin, it functions in modulation of the microbiota and immunomodulation.

However, *P. acnes* can act as an opportunistic pathogen, causing inflammatory responses by secreting a host-tissue component that degrades enzymes such as cytotoxic cAMP factors.[7] This can be seen in disease processes, such as acne vulgaris and shoulder infections, and there has even been some speculation that it has some involvement in the pathogenesis of prostate cancer. This organism, which was historically dismissed as a contaminant that did not necessitate treatment in revision shoulder surgery, appears to significantly contribute to shoulder pain, stiffness, and component loosening without displaying the overt signs of periprosthetic infection.[8] It is poorly understood why *P. acnes* exhibits parasitic properties, but it appears that certain strains, or phylotypes, exhibit these inflammatory properties more so than do others. The inflammatory response exhibited by *P. acnes* certainly has some relation to the host cell type-specific response, as well.[7] Additionally, *P. acnes'* ability to form an antibiotic resistant biofilm enables its ability to be eradicated unless prosthesis exchange and prompt antibiotic therapy are initiated.[9,10] Further research is currently being performed on *P. acnes* in regards to both its mutualistic and parasitic properties.[7]

Staphylococcus epidermidis, such as *P. acnes*, has evolved over time with the human host.[6,7] Similar to *P. acnes*, it is considered a mutualistic part of the skin flora, acting against more pathogenic organisms on the skin, such as *S. aureus*, and on *P. acnes* in instances of overgrowth, such as acne vulgaris.[6] However, this particular organism is considered an opportunistic pathogen when it breaches the skin surface. It is the leading cause of hospital-acquired infections and bacteremia, mostly associated with medical device use in immune-compromised patients.[7] Similar to *P. acnes,* its pathogenesis relies on the creation of multilayered biofilms that allow it to attach to foreign bodies and host tissue enabling it to resist to host clearance. Some strains even contain the methicillin resistance gene, *mecA*, further enabling its pathogenic abilities.[7]

Risk Factors

Risk factors for deep infection following shoulder arthroplasty include patient sex, age, indication for the procedure, type of arthroplasty performed, and number of procedures performed on the shoulder prior to arthroplasty.[11,12] In a retrospective cohort study of 3,906 subjects undergoing primary shoulder arthroplasty, Richards and colleagues[11] found no association with deep infection rate and ASA score, BMI, diabetes mellitus, or race. However, this group reported that with every one-year increase in age, a 5% lower risk of infection was observed. In parallel to many other studies, men were 2.59 times more likely to have a postoperative deep infection following arthroplasty. Arthroplasties performed in the setting of trauma were 2.98 times more likely to develop postoperative infection. Additionally, patients undergoing reverse total shoulder arthroplasty had a 6.11 greater risk of infection compared to those undergoing primary unconstrained total shoulder arthroplasty.[11] Contrary to these findings, in a retrospective study following 814 shoulder arthroplasties, Florschutz and associates[12] found no significant difference in infection rates when comparing primary reverse total shoulder arthroplasty to primary anatomic total shoulder arthroplasty. However, they found that subjects who had previously undergone non-arthroplasty procedures prior to initial anatomic and reverse total arthroplasties had a 3.35 and 4.8 higher risk of infection, respectively, compared to subjects who had never undergone non-arthroplasty procedures prior to their index arthroplasty.[12]

General Considerations

Many considerations have been examined in regards to prevention of orthopaedic infection. Multiple studies have shown that decreased operative time, operating room traffic, and room noise have been effective means of reducing orthopaedic infections.[13-18] Additionally, Dalstrom and colleagues demonstrated a time-dependence in regards to the length of time that operating-room trays were opened and the rate at which they became contaminated.[13] While wound irrigation conceptually would seem to reduce infection rates, there have been conflicting results in regards to surgical site infection prevention.[14,15]

Hand washing has been reported as the single most effective measure for minimizing infection.[16] In comparing three traditional types of scrub, both alcohol and chlorhexidine have proved to be more potent than povidone-iodine scrubs in reducing CFUs. Alcohol has proved to be more potent in reducing CFUs; however, chlorhexidine has the ability to bind longer to the skin. In a study by Parienti and coworkers, chlorhexidine prevented the return to normal bacterial levels for up to 6 hours post scrub. In regards to a traditional scrub versus the used of aqueous rubs, a randomized control trial in France in 2002 demonstrated no difference in infection rates when comparing a 5-minute traditional chlorhexidine scrub to the use of an aqueous dry scrub after nonsterile hand washing.[17] In addition to hand washing, frequent glove changing, especially after draping takes place, has been found to significantly reduce the rate of surgical site infections.[18] Multiple studies have shown that surgical exhaust gowns provide a significant decrease in bacterial colony forming units; however, this has not correlated with a decrease in the effectiveness of preventing wound contamination.[19,20]

Skin Preparation

Multiple studies have demonstrated the improved efficacy of surgical site preparation with chlorhexidine, compared to iodine containing scrubs.[21-23] Saltzman and colleagues cultured the skin immediately after skin preparation and found the culture positive rate to be much lower with chlorhexidine (7%) compared to povidone-iodine scrub (31%); however,

neither agent proved to be more effective over the other in regards to elimination of *P. acnes* from the shoulder region.[21] The reason for chlorhexidine's ineffectiveness at eliminating *P. acnes* might be due to the fact that this organism resides primarily in the dermal layer. Lee and coworkers performed dermal punch biopsies in 10 healthy male individuals after skin preparation with chlorhexidine gluconate and found 70% of these individuals to be positive for *P. acnes*.[24] Sethi and associates studied subjects undergoing index shoulder arthroscopies to evaluate for the presence of *P. acnes*.[25] After performing a skin preparation, which included using a scrub brush containing 3.3% chloroxylenol followed with three applications of 2% chlorhexidine gluconate, skin swab cultures were taken before skin incision and at the conclusion of the operation. Three intraoperative deep tissue cultures were taken, as well. Skin cultures were positive for *P. acnes* in 15.8% of the subjects immediately following skin preparation. This number of subjects increased to 40.4% by the end of the operation. Of all 57 subjects in the study, 32 subjects (56%) had at least one positive culture for *P. acnes*.[25]

Hudek and colleagues took skin, superficial, and deep tissue samples in 118 subjects undergoing their index open shoulder procedure. Of these 118 subjects, 43 (36.4%) had at least one positive culture for *P. acnes*.[26] Two recent prospective studies have demonstrated the incidence of *P. acnes* in open shoulder surgery and shoulder arthroscopy. In a study by Mook and coworkers, after performing skin preparation with a scrub brush filled with 4% chlorhexidine gluconate followed by cleaning with an ethyl-isopropyl alcohol solution and final preparation with 2% chlorhexidine gluconate and 70% isopropyl alcohol paint, three periscapular tissue cultures were taken in patients undergoing an open deltopectoral approach. Of 82 patients who had not previously undergone shoulder surgery, the cultures of 14 (17.1%) were positive for *P. acnes*.[27]

Chuang and associates[28] found similar results in 51 patients undergoing index shoulder arthroscopy. These patients underwent skin preparation with a 5-minute scrub with 4% wt/vol chlorhexidine solution followed by application of 2% chlorhexidine gluconate and 70% isopropyl alcohol. After labral or rotator cuff repair was performed, deep tissue cultures were taken from around the surgical site. Ten of 51 (19.6%) deep tissue cultures were positive for *P. acnes*.[28] While standard skin preparation has not proved to provide adequate coverage for *P. acnes*, using a standard benzoyl peroxide based preparation has been shown to minimize the rate of positive cultures in both the skin and deep tissues. In a study by Sabetta and colleagues, 50 patients were treated with topical 5% benzoyl peroxide cream for 48 hours prior to undergoing arthroscopic shoulder surgery. These patients then underwent skin preparation with a 3.3% chloroxylenol scrub and 2% chlorhexidine paint. Skin cultures were taken before and after incision. Additionally, joint aspirates and deep cultures were taken. Twenty-five of 400 (6.25%) skin cultures were positive after skin preparation. This number percentage increased to 10% at the conclusion of surgery. Only 6% of deep tissue cultures and 4% of joint aspirates were positive. This culture positive rate was equivalent with the air control swab. Additionally, there was no difference in rates of positive cultures found in males versus females, and none of these patients were displaying signs or symptoms of shoulder infection at 9-month follow-up.[29]

Adhesive Drapes

While the idea behind applying adhesive drapes, especially those impregnated with iodophor, to the skin after surgical site preparation would seem to reduce infection rate, multiple studies have not proven this to be true.[30]

Preoperative Hair Shaving

Similar to the use of adhesive drapes, preoperative hair shaving would seem to reduce the bacterial load around surgical sites; however, at least one study has proved to be quite the contrary. Maracek and colleagues found that removal of axillary hair had no effect on the bacterial burden of *P. acnes*. Additionally, clipped axillae had a higher total bacterial burden than did unclipped axillae.[5]

Incision Site

While both Saltzman and coworkers[21] and Lee and associates[24] both showed the ineffectiveness of surgical skin preparation, Saltzman and coworkers[21] and Hudek and colleagues[26] further compared the rate of culture positivity at certain aspects of the shoulder. Saltzman found that after skin preparation with ChloraPrep®, bacteria grew on the culture from 10% of the specimens taken from either an anterior or posterior arthroscopic portal site.[21] Hudek and colleagues compared standard approaches to open shoulder procedures and found that the relative risk for obtaining a positive *P. acnes* culture was two-fold greater at the incision site for the anterolateral approach than for the deltopectoral approach.[26]

Antibiotics

There have been no studies related to infection in shoulder surgery and the administration of prophylactic antibiotics; however, multiple studies in the total joint arthroplasty literature have demonstrated the effectiveness of preoperative administration of cefazolin or cefuroxime prior to incision. Vancomycin is recommended for use in patients with prior history of methicillin resistance *Staphylococcus aureus* infection or colonization.[31,32] While many shoulder arthroplasties are performed with a press-fit technique rather than with bone cement, Nowinski and coworkers[33] studied the effect of the use of antibiotic-loaded cement and its effect on deep infection. This multi-institutional, retrospective study compared the infection rate in 265 reverse shoulder arthroplasties that had humeral component fixation with standard bone cement to 236 shoulders that had humeral component fixation with cement impregnated with tobramycin, gentamycin, or vancomycin/tobramycin. At an average follow-up of 37 months, the infection rate in the standard cement group was 3.0% (8/265) versus 0% in the antibiotic-impregnated

cement group. There was no evidence of osteolysis, prosthesis loosening, or altered biomechanical properties in the antibiotic-impregnated group.[33] Lovallo and associates[34] retrospectively looked at the effect of intra-articular gentamicin injection into the glenohumeral joint following total shoulder arthroplasties. The infection rate in those receiving the injection was 0.29% (1/343 patients) versus 3% (5/164 patients) in those who did not receive a postoperative intra-articular injection.[34]

Conclusion

Infection following shoulder surgery is a devastating complication. While previous reports have shown that the most common organisms found in deep infection are Gram-positive aerobic bacteria, multiple recent studies have demonstrated that *P. acnes* may be more prevalent. Many studies in the orthopaedic literature have shown that hand washing, decreasing operative time, routine glove changing, minimizing operating room traffic, and covering instruments can decrease the risk of deep infection. And while chlorhexidine appears to be the most efficacious skin preparation agent, it still has minimal effect on eradication of *P. acnes* from the surgical site. Preoperative topical applications of benzoyl peroxide have shown promise in decreasing the rate of *P. acnes* culture positivity. Hair clipping and the use of adhesive drapes may have little effect on decreasing the incidence of deep infection. The relative risk of obtaining a positive *P. acnes* culture is twice as high with the anterolateral approach than with the deltopectoral approach. The use of antibiotic impregnated cement and intra-articular gentamicin immediately postoperatively seem to be an effective means of preventing deep infection. As suggested by Lee and colleagues, further strategies need to be developed for preventing *Priopionibacterium* contamination of surgical wounds by addressing the bacteria both on and in the skin at the surgical site.[24]

Stemless and Short Stem Humeral Components in Shoulder Arthroplasty

Howard D. Routman, D.O., Lisa Becks, M.S., and Christopher P. Roche, M.S., M.B.A.

Abstract

Humeral-sided arthroplasty design evolution continues to be supported by the published literature in the transition away from traditional stemmed devices. Early studies have shown not only absence of failure with these newer shorter and stemless designs but also equivalence in terms of early outcomes compared to traditional stemmed devices with the benefits of shorter operative time, less blood loss, easier revision, and the potential to reduce stress shielding and periprosthetic fractures. We will review the literature available on the different designs of both short stem and stemless humeral devices.

Shoulder arthroplasty design has undergone continuous evolution since the original monoblock design of Neer. Current humeral stem designs are frequently modular, to allow for intraoperative decisions made by the surgeon to dictate the final sizing of the device based on individual patient variables. However, even with maximum stem modularity in its current form, there are still situations of metadiaphyseal deformity that make using a stemmed device very difficult. In addition, while loosening of a humeral stem in the absence of infection is uncommon, other stem-related problems do exist in shoulder arthroplasty. Stem related issues can be divided into intraoperative and postoperative problems. In response to these clinical issues and industry market-related challenges, there has been a period of rapid growth of short stem and stemless devices for humeral-sided arthroplasty. We will review the literature available on these different designs.

Howard D. Routman, D.O., Atlantis Orthopaedics, Palm Beach Gardens, Florida. Lisa Becks, M.S., and Christopher P. Roche, M.S., M.B.A., Exactech, Inc., Gainesville, Florida.

Correspondence: Howard D. Routman, D.O., F.A.O.A.O., Atlantis Orthopedics, 130 JFK Drive, Suite 201, Atlantis, Florida 33462; hdr@floridashoulder.com.

Historically, humeral stems have progressed from monoblock components designed for cemented fixation to modular coated devices for press-fit application. Intraoperative complications associated with the use of a stem include humeral shaft fracture during preparation, insertion, or removal; difficulty removing a well-fixed stem either because of aggressive coating or because of cement fixation during revision surgery necessitating humeral shaft osteotomy; and malalignment of the metadiaphyseal portion of the humerus requiring tuberosity osteotomy in cases of post-traumatic deformity.[1,2] The natural offset from the intramedullary axis of the humerus and the center of rotation of the humeral head can lead some surgeons using stemmed devices to malposition the humeral head as well, resulting in altered joint kinematics and rotator cuff dysfunction. Problems that surgeons encounter after insertion of a stemmed device include proximal bone loss from stress shielding, postoperative periprosthetic fractures, osteolysis from polyethylene debris, and prosthetic loosening.

Additionally, the rapid growth of stemless devices has been driven by market factors. Specifically, manufacturers with only third generation shoulder prostheses, as opposed to fourth generation prostheses, are unable to completely reproduce the proximal humeral anatomy. This is most obvious in the inability of these prostheses to accurately reproduce a patient's humeral neck angle in a continuous manner: third generation systems attempt to reproduce neck angle in a costly manner by providing multiple stemmed devices at defined neck angles that may or may not correspond to the patient's actual humeral neck anatomy or to that of the osteotomy. Stemless devices are less expensive from an inventory perspective because of the reduced modularity, as they do not require different neck angles and require a smaller scope to reproduce the anatomy without concern for intramedullary

canal size, which commonly varies between 7 mm to 17 mm in diameter.

Short Stem Review

The uncemented short stem prosthesis is a bone preserving design, and if the short stem is a platform or convertible design, it also has the potential to have a simplified revision option to or from anatomic and reverse shoulder arthroplasty. Stable proximal fixation of the short stem prosthesis is typically achieved by compaction of metaphyseal cancellous bone.

No mid-term or long-term follow-up is currently published for short stem devices. After 2 years of follow-up, 44 Aequalis Ascend patients demonstrated improvement in Constant and pain scores with few complications and exhibited clinical results comparable to those of established prosthetic systems.[3] A radiographic assessment showed 13.6% of cases with slight stress shielding at the medial cortex, but no stem subsidence was found.[3] Similarly, the Biomet Comprehensive "mini" stem (83 mm length) underwent a retrospective study with 44 patients who underwent a primary rTSA.[4] At a mean follow-up of 27 months, pain was rated as mild or none in 97.7% of shoulders, patients had improved range of motion and improved Neer scores with 95.4% being excellent or satisfactory, and there was no radiological evidence of loosening of the humeral stem in any patient.[4]

Stemless Design Review

Stemless designs completely avoid diaphyseal instrumentation and fixation and resect the humeral head at the anatomic neck. Designs for fixation range from threaded central cages to larger coated metaphyseal derotational fins with or without a collar that can sit on the cut surface of the humeral head. These devices are ideally suited for younger patients in which revision can be expected in the future in order to preserve bone stock and also for deformity cases where even short stem devices would not be useful without a realigning tuberosity osteotomy. Because of the anatomic neck osteotomy utilized by stemless devices, the humeral head resection allows for easier exposure to resurface the glenoid, as compared to humeral head resurfacing, though it is less bone preserving.

While stemless devices remove less overall bone than stemmed devices, they likely remove more metaphyseal bone as that bone is exclusively relied upon for fixation. As some stemless devices do not permit the use of both aTSA and rTSA, these devices may need to be removed at revision to a rTSA. Given that more metaphyseal bone is likely removed, it is important to recognize that the fixation in revision surgery may be compromised by the use of a stemless device at the primary surgery.

The TESS device was first reported in 2010 to improve range of motion, as well as Constant, WOOS, and DASH scores.[5] Intraoperative fractures did occur during the early learning curve while inserting this device, none of which were recognized at the time of surgery and all of which healed uneventfully.[5] In comparative studies against the Neer II and Bigliani-Flatow devices, the TESS fared well and had similar outcomes for osteoarthritis.[6] In a comparison to patients with a stemmed device, Mathys Affinis and TESS stemless patients had less blood loss and a shorter operative time.[1]

The Biomet Nano device is the next generation of the TESS device with a 6-armed corolla that impacts into the metaphysis and mates with the head via a screw-in Morse taper device. It has been designed as a platform stem, allowing both anatomic and reverse arthroplasty from the same metaphyseal fixation. This device has been in use in Canada for some time and is currently under FDA evaluation for use in the USA, however, no clinical outcomes have been published.

Habermeyer and coworkers recently reported on the use of 233 stemless Arthrex Eclipse implants with an average follow up of 23 months.[7] Improvements in the Constant score with only one case of loosening was found. However, periprosthetic fractures were not eliminated by the use of a stemless device. A more recent study from this group with longer follow-up (mean: 72 months) continued to support the use of the device; however, there was a 9% revision rate and a 12.8% complication rate.[8]

Finally, the Tornier Simpliciti and Zimmer Sidus implants both feature coated derotational fins with a collar. The Tornier Simpliciti recently gained 510k clearance with clinical data, and the Zimmer device is currently under investigation by the FDA, both have been sold in Europe for several years.

Conclusion

As a result of the recognition of their clinical utility, stemless and short-stemmed humeral-sided devices are available and traditional longer-stemmed devices may see a decrease in usage. Short-term clinical follow-up studies have shown not only absence of failure with these newer shorter and stemless designs but also equivalence in terms of early outcomes compared to traditional stemmed devices with the benefits of shorter operative time, less blood loss, and the potential to reduce stress shielding, and periprosthetic fractures. However, none of these devices have documented long-term clinical follow-up, the ease of revision is relatively undocumented, and the stress transfer relationship with metaphyseal bone is unknown. For these reasons, longer-term clinical follow-up is necessary to confirm these promising initial experiences and demonstrate that these short-term results hold-up over time.

The Subscapularis-Sparing Approach in Humeral Head Replacement

Felix H. Savoie III, M.D., and Michael J. O'Brien, M.D.

Abstract

Introduction: Failure of the subscapularis repair can be detrimental to patient outcome and shoulder function in shoulder replacement surgery. This report details an approach to resurfacing the humeral head that preserves the majority of the subscapularis attachment to the humerus, allowing a more rapid rehabilitation and minimizing postoperative subscapularis insufficiency.

Methods: In this approach, only the inferior 30% to 50% of the subscapularis tendon is detached from the humerus, leaving the critical superior aspect of the tendon attached to the lesser tuberosity. In a previous study, we evaluated this approach in 43 patients. Nineteen had postoperative magnetic resonance imaging (MRI), and 24 patients had ultrasound (US) evaluation. Physical examination included belly press and lift-off tests; follow-up included visual analog scale (VAS), American Shoulder and Elbow Surgeons (ASES), Constant, UCLA, Rowe, and SF-12 scores.

Results: All patients had a minimum 2-year follow-up (range 2 to 6, average 4). All patients had subscapularis strength equal to the opposite side as measured by lift-off, belly press, and bear hug tests. Average postoperative scores included ASES, 74.4; Constant, 78.3; UCLA, 27; Rowe, 81.7; and VAS, 2.2; SF-12 averages all showed statistically significant improvement except for general health, which showed improvement approaching significance. All had an intact subscapularis tendon attachment as evaluated by either MRI or US imaging. None had atrophy in the muscle belly.

Conclusions: The subscapularis-sparing, minimally-invasive approach to the glenohumeral joint provides adequate exposure for shoulder replacement surgery and provides a decreased risk of postoperative failure (rupture or atrophy) of the subscapularis tendon.

Felix H. Savoie III, M.D., and Michael J. O'Brien, M.D., Department of Orthopaedic Surgery, Tulane University, New Orleans, Louisiana.

Correspondence: Felix H. Savoie III, M.D., fsavoie@tulane.edu.

The deltopectoral approach with subscapularis tenotomy represents a standard approach to the glenohumeral joint with mostly satisfactory outcomes reported in the literature.[1] Failure and dysfunction of the repaired subscapularis remains a concern after both tenotomy and lesser tuberosity osteotomy, despite multiple variations in subscapularis takedown and reattachment techniques, with incidence reported as high as 40% in some studies.[2-8] In addition to failure of the reattachment of the tendon, neurologic atrophy and fatty infiltration of the muscle belly may also be a cause of pain and functional impairment.[9-11] Montgomery and colleagues described the subscapularis split and repair with suture anchors as a way to avoid taking down the subscapularis during open capsulolabral repair in athletes.[12] We have been concerned about the propensity for subscapularis detachment for many years and have sought an alternative, mini-open approach that would allow shoulder replacement without taking down the entire tendon. We recently reported on our results with this technique with excellent success in preserving subscapular function.[13]

Materials and Methods

Preoperative Data

All of the patients considered for this study were treated for glenohumeral arthritis and had failed conservative treatment, where each patient decided to schedule glenohumeral joint replacement surgery. Inclusion criteria for this study consisted of Grade III degenerative changes of the shoulder, failure of nonoperative therapeutic measures, and a willingness to undergo this subscapularis-sparing procedure.[4-16] Exclusion criteria were glenoid asymmetry (Walch B2 or C glenoid),

Savoie FH 3rd, O'Brien MJ. The subscapularis-sparing approach in humeral head replacement. Bull Hosp Jt Dis. 2015;73(Suppl 1):S148-53.

unwillingness to undergo the procedure, unwillingness to complete the postoperative questionnaire, or participate in the examination.[17,18]

In the previously published study, we included 29 males and 21 females, with 27 right shoulders and 23 left shoulders. The mean patient age was 63.2 years (range: 32 to 87). Of the 50 patients, 7 were withdrawn for reasons of severe physical illness unrelated to the shoulder (1), patient's decision (4), and other reasons (2). All 7 of these patients had intact subscapularis function postoperatively at last clinical follow-up but were not included in the follow-up study data. Outcome measures included age, active and passive shoulder range of motion, visual analog scale (VAS) pain level, and the following rating scales: American Shoulder and Elbow Surgeons (ASES), Rowe, Constant, modified UCLA, and SF-12. All outcomes measures were collected by independent evaluators blinded to the procedure and not by the operative surgeons. The preoperative physical exam included the lift-off, belly-press, and bear hug tests.[3,19,20]

Operative Technique

All patients were positioned in the beach chair position and placed under general anesthesia in combination with an interscalene block. Prophylactic antibiotics were administered prior to incision. A 5 cm to 7 cm vertical incision was made utilizing a standard deltopectoral approach. The long head of the biceps is located at the top of the pectoralis major tendon and followed up through the rotator interval, which is released between the supraspinatus and subscapularis, thus allowing the biceps to be released off the superior labrum. (In posttraumatic patients under 30, we try to preserve the biceps and do not routinely perform a release and tenodesis). The subscapularis tendon is identified, and a split is made in the lower muscle tendon raphe,

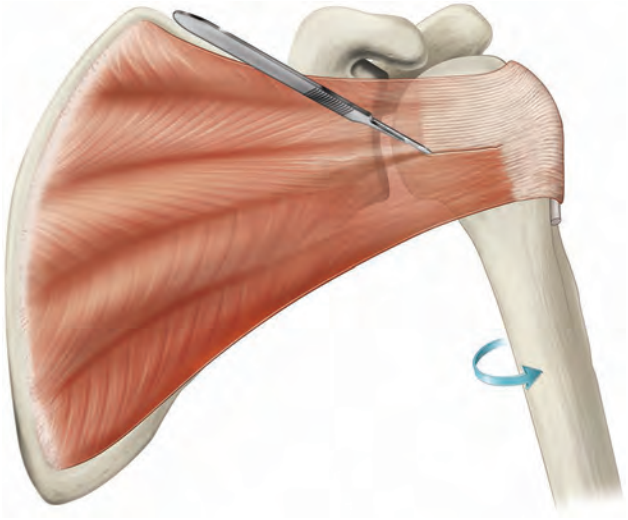

Figure 1 A horizontal split is made in the lower one-third to one-half of the subscapualris.

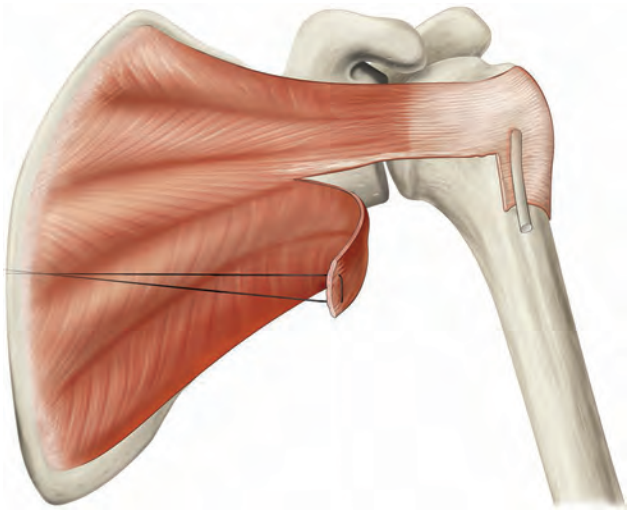

Figure 2 The lower split portion of the subscapularis is reflected; the longitudinal part of the incision is taken inferiorly following the medial ridge of the bicipital groove.

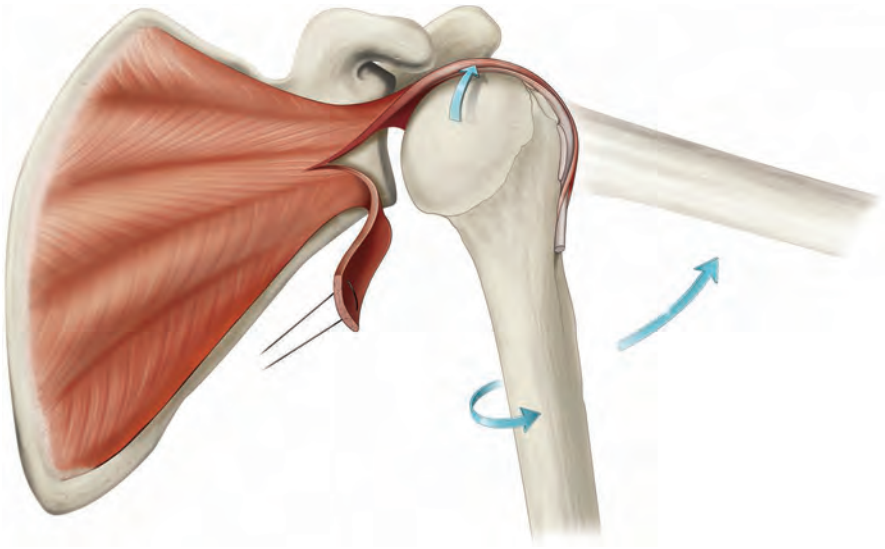

Figure 3 The inferior subscapularis flap is continued medially, exposing the degenerative humeral head. The upper subscapularis muscle is flipped over the superior aspect of the humeral head as the arm is continued to be abducted and externally rotated, exposing the humeral head.

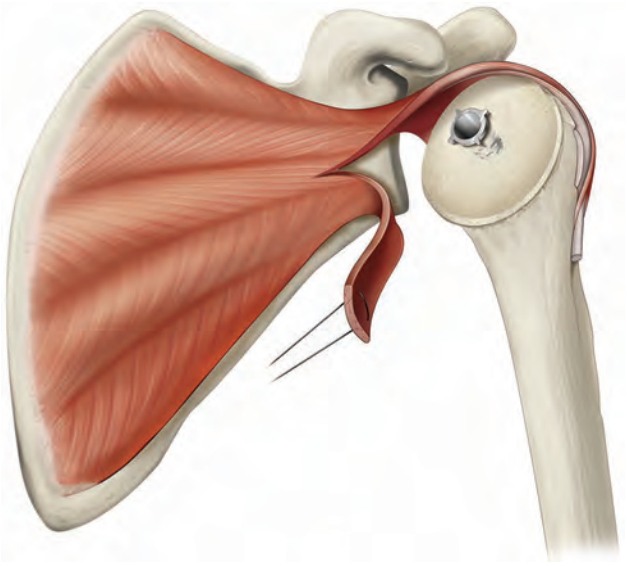

Figure 4 Preparation of the resurfacing humeral head under the superior subscapularis; the humeral head is reamed, and the cage peg is inserted prior to impaction of the resurfacing humeral head bearing surface.

which is located in the lower one-half to lower one-third of the muscle tendon unit (Fig. 1). Electrocautery is used to follow a line straight down the humerus on the medial ridge of the biceps groove to the pectoralis major insertion. This leaves the tissue along the lateral groove as a potential anchor for future soft tissue repair. The inferior one-third to one-half of the subscapularis is elevated off the lesser tuberosity and a soft tissue sleeve continues around the inferior humerus subperiosteally (Fig. 2). It is important to continue the release medially under and around any inferior humeral spurs in order to protect the axillary nerve. As the soft tissues are released, the arm is continually and slowly externally rotated and abducted to allow exposure of the inferior humeral head. The soft tissue and capsule release is continued under the teres minor and lower infraspinatus attachments to the humerus, without detaching the tendons and allowing more flexibility of the glenohumeral joint. Once the release is complete, a Cobb retractor is used to "flip" the upper subscapularis muscle over the superior aspect of the humeral head as the arm is continued to be abducted and externally rotated, exposing the humeral head (Fig. 3). A Chandler retractor is placed medially and a Hohmann retractor superiorly under the preserved upper subscap and supraspinatus for protection, allowing complete exposure of the humeral head. All inferior osteophytes are removed, and the humeral head is either reamed for resurfacing or cut for humeral head replacement (Fig. 4). The humeral head may be dislocated inferiorly to expose the glenoid, and if cut, the shaft is retracted posterior and inferior for glenoid exposure. The glenoid is replaced first in standard fashion, followed by the humerus. After resurfacing, the arm is adducted and internally rotated to allow the head to relocate into the glenoid. The preserved upper subscapularis tendon is easily visualized. The lower subscapularis tendon is then repaired with either #2 Ethibond to the soft tissue preserved along the bicipital groove or with a double-loaded suture anchor and a double-row repair technique (Fig. 5) and interrupted polydioxanone, (Johnson & Johnson Ethicon®) sutures to reinforce the repair, both in the split raphe and at the distal tendon insertion. All patients are placed into a sling with an abduction pillow in the operating room prior to awakening from anesthesia.

Postoperative

Radiographs taken in the recovery room and all postoperative visits are used to confirm proper implant positioning. Postoperatively, passive range of motion and active external rotation exercises were started at 1 week, and active internal range of motion exercises were started at 3 weeks with discontinuation of the sling. Physical therapy

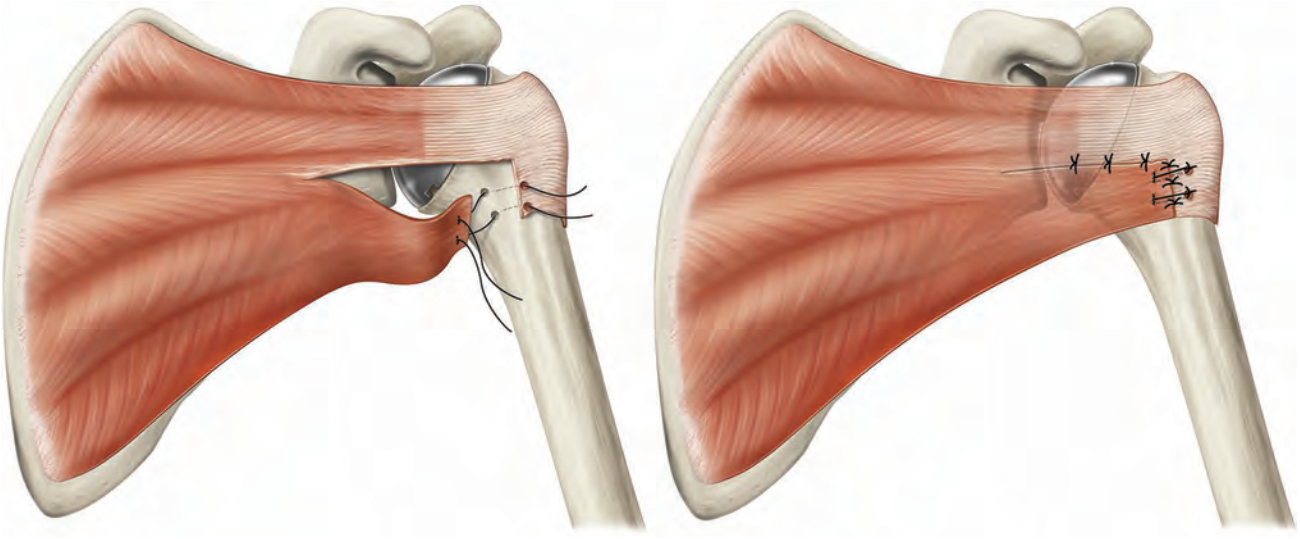

Figure 5 Subscapularis repair after humeral head resurfacing.

was allowed to progress as tolerated beginning at 4 weeks, with most patients resuming gym workouts at that time.

Results

Preoperative Data from the Original Study

Initial radiographs showed Grade III or Grade IV arthritic changes, with bone contacting bone, on the axillary view in all cases. The degree of degenerative change was also measured on preoperative MRI or computed tomography (CT) or both as Grade III or IV in all cases.[15]

The preoperative evaluations showed a mean ASES score of 16.7; UCLA, 10.1; Rowe, 44.4; and Constant, 24.2. The mean preoperative scores on the SF-12 were as follows: physical functioning, 32.6; role-physical, 37.5; bodily pain, 27.3; general health, 53.5; vitality, 33.7; social functioning, 49.4; role-emotional, 39.8; and mental health, 42.2. The mean preoperative score on the VAS pain scale was 7.8 on a scale ranging from 0 to 10.

Postoperative Data from the Original Study

All patients had a negative belly push-off and lift-off test at 4 weeks postoperatively. All patients had a physical examination and completed questionnaires at 2-year follow-up or more postoperatively to ascertain the condition of the subscapularis tendon. The mean length of follow-up was 48 months (range: 24 to 60 months). Of the 43 patients who were willing to be included in the study and return for reimaging, 19 received MRI scans formatted to evaluate the tendon and muscle of the subscapularis while minimizing "scatter." The remaining 24 patients underwent ultrasonography from a trained ultrasonographer to evaluate the attachment of the subscapularis, the inferior repair, and the amount of atrophy, if any, present in the muscle of their operative shoulder. The same measures and rating scales (including the SF-12) collected preoperatively were collected postoperatively for all 43 patients who returned.

Statistical Methods

All data were independently tested for clinical significance by the use of Wilcoxon signed-rank test of variance to analyze the hypothesis that there was an improvement from baseline to follow-up and to quantify the effectiveness of the approach.

Final Follow-Up Examination and Imaging

The ability to perform lift-off, bear hug, and normal belly-press tests was present in all 50 patients (43 included in the study and the 7 withdrawn) at 1 month postoperatively. All three tests have remained normal throughout follow-up in all patients, and all three tests were still negative in the 43 who returned for final evaluation.

All patients improved after the subscapularis-sparing deltopectoral procedure with humeral head resurfacing. Most patients noticed an initial improvement, and all have continued to improve over the lifetime of the replacement. There were no cases of instability postoperatively; however, there was one postoperative surgical wound dehiscence. This patient underwent a formal incision and drainage and closure; intraoperative cultures remained negative. No other patients have required reoperations after their initial shoulder replacement. These data lead to an overall success rate of 100% for subscapularis repair following humeral head replacement using a minimally invasive subscapularis-sparing approach.

The mean ratings of the entire group at final follow-up were as follows: ASES, 74.4 (preoperatively, 16.7; $p < 0.0001$); UCLA, 27.0 (preoperatively, 10.1; $p < 0.0001$); Rowe, 81.7 (preoperatively, 44.4; $p < 0.0001$); and Constant, 78.3 (preoperatively, 24.2; $p < 0.0001$). The postoperative SF-12 scores were physical functioning, 64.5 (preoperatively, 32.6; $p = 0.0001$); role-physical, 66.0 (preoperatively, 37.5; $p = 0.009$); bodily pain, 73.3 (preoperatively, 27.3; $p < 0.001$); general health, 61.9 (preoperatively, 53.5; $p = 0.1615$); vitality, 53.5 (preoperatively, 33.7; $p = 0.002$); social functioning, 79.7 (preoperatively, 49.4; $p = 0.0005$); role-emotional, 78.2 (preoperatively, 39.8; $p = 0.0002$); and mental health, 72.7 (preoperatively, 42.2; $p < 0.0001$). The mean VAS pain score was 2.2 (preoperatively, 7.8; $p < 0.0001$). Thus, all parameters showed statistically significant ($p < 0.05$) improvement except for the general health category in the SF-12, which showed improvement approaching significance.

Postoperative Imaging

MRI with special sequencing to show the subscapularis muscle and tendon while minimizing implant "scatter" was performed in 19 of the 43 shoulders at 2 to 5 years postoperatively and showed an intact subscapularis tendon and absence of neuromuscular atrophy or fatty infiltration in all 19 patients.[3,4,21,22] Similarly, the ultrasound evaluation of the remaining 24 patients revealed an intact subscapularis tendon without muscle atrophy. These were specific areas of interest due to the lower tendon being very thin and the previous documentation of muscular atrophy or tearing in multiple previous studies of the subscapular tendon after tenotomy.[4,5,10,11,22,23]

Discussion

The physical examination and imaging in our group of patients showed that postoperative muscle, tendon, and strength were normal. Subscapularis takedown does provide an excellent exposure to the shoulder joint during open procedures. The actual incidence of postoperative subscapularis rupture after open surgical takedown is unknown but seems to be an underreported problem. Jackson and colleagues evaluated 15 asymptomatic total shoulder arthroplasty (TSA) patients by ultrasound and found 7 of the 15 had significant failure of the repaired subscapularis tendon.[23] Concerns about maintaining the functional integrity of the subscapularis in athletes are what led Montgomery and coworkers to develop the subscapularis split technique for open capsule-labral work.[12] Other investigators have

shared these concerns about subscapularis failure after open surgery, but the norm during arthroplasty has always been that complete takedown is necessary for exposure due to preoperative stiffness and motion loss. Various techniques have been developed to improve subscapularis healing, including lesser tuberosity osteotomy, varying suture patterns, and soft tissue reinforcement techniques.[21,24-30] Lafosse and associates described TSA through the rotator interval without detaching any of the subscapularis but was limited by an inability to remove inferior humeral spurs via this approach.[31] Simovitch and colleagues recently discussed TSA using a subscapularis preservation technique in which they combined the Lafosse technique with one similar to that used in the present study with satisfactory results in three cases.[32] Gerber and colleagues reported that postoperative subscapularis insufficiency appears to be lessened with lesser tuberosity osteotomy; however, increases in fatty infiltration were seen in 49% patients and failure and weakness to belly press in 11% of patients.[4,7,33] Lapner and coworkers compared lesser tuberosity osteotomy with subscapularis peel in a series of patients and found no significant differences, although the primary outcome measure was the belly press test with a hand held dynamometer; no postoperative imaging of the subscapularis was attempted.[21] Despite these advances, subscapularis failure remains a difficult problem to prevent and treat and can lead to instability, weakness, pain, and early failure in shoulder arthroplasty.[5,6,11,23,34] Postoperative fatty infiltration of the subscapularis may also cause dysfunction and is seen after both subscapularis tenotomy and lesser tuberosity osteotomy.[22]

Preserving upper one-half to upper two-thirds of the subscapularis (which accounts for 70% or more of the strength and function of the muscle-tendon unit), while still allowing complete access to the humeral head and glenoid, could potentially avoid subscapularis insufficiency. Approaching the humerus through an inferior subscapularis interval allows removal of the inferior humeral head spurs, capsular release, and access to the glenoid via both the inferior subscapularis interval and the rotator interval while preserving the majority of the subscapularis. It also provides a soft tissue sleeve to protect the axillary nerve from injury during the operation.

Key technical points in the approach include:

1. Open the rotator interval by following the biceps tendon superiorly;
2. The initiating point for the inferior takedown is along the medial ridge of the bicipital groove;
3. The entire flap is elevated as a unit subperiosteally around the humerus to the posterior aspect of the humeral shaft inferior to the humeral spurs to maintain soft tissue protection of the axillary nerve;
4. Complete all capsular release or excision from within the interval to obtain full motion of the glenohumeral joint; and
5. Secure repair of the lower portion of teh subscapularis can be performed with an anchor(s), suture, or both.

We believe that preserving the upper one-half to upper two-thirds of the subscapularis allows a much more rapid postoperative rehabilitation to regain motion and strength while minimizing the risk of atrophy or detachment, as seen in the previous study in which our accelerated rehabilitation program did not result in detachment of the repair.

Conclusion

In conclusion, shoulder replacement with preservation of the upper subscapularis provides adequate exposure to allow humeral head resurfacing. When the upper border of the subscapularis insertion is left intact, there is a decreased risk of postoperative failure or rupture of the subscapularis tendon, even with the more rapid rehabilitation employed for these patients.

Subscapularis Preserving Technique in Anatomic Total Shoulder Arthroplasty

The Superior and Inferior Approach

Ryan Simovitch, M.D., Robert Fullick, M.D., and Joseph D. Zuckerman, M.D.

Abstract

Subscapularis tenotomy for anatomic total shoulder arthroplasty has been the standard approach for shoulder surgeons that use the deltopectoral approach. The risk of subscapularis insufficiency after this approach has been well documented. In order to avoid subscapularis complications, subscapularis sparing approaches through the rotator interval have been developed. We present two alternative subscapularis preserving techniques that are performed through the deltopectoral interval and allow more complete osteophyte excision and accurate humeral head sizing. These techniques require modified instrumentation and are facilitated by the use of an adaptable prosthesis with dual eccentricity. Future studies will examine the comparative clinical and radiographic outcomes of these techniques.

The incidence of anatomic total shoulder arthroplasty (aTSA) performed in the USA is rapidly increasing.[1] Despite innovation in shoulder prostheses favoring a more anatomic and precise reconstruction, the standard approach for aTSA still requires exposure through the subscapularis and subsequent repair at the conclusion of the shoulder arthroplasty. The violation and repair of the subscapularis limits postoperative physical therapy protocols, requires protection in a sling, restricts initial use of the operative arm for activities of daily living (ADL), and poses a risk for inadequate healing. Subscapularis dysfunction and inadequate healing are reported to be common in the literature. Subscapularis insufficiency after aTSA has been linked to pain, poor function, and instability.[2-5] It is a potential cause for the need for revision.[6]

Lafosse and colleagues reported mid-term follow-up of a subscapularis sparing aTSA approach through a deltoid split.[7] This technique utilized a rotator interval window. Although clinical results were good, radiographic outcomes were suboptimal with non-anatomic humeral head osteotomies, residual inferior humeral neck osteophytes, and humeral head under-sizing being frequently found problems.

We have utilized two different modified subscapularis preserving approaches that when coupled with an adaptable implant (Equinoxe®, Exactech, Inc., Gainesville, FL) and specially designed instruments provides excellent exposure, allows anatomic reconstruction, and significantly eliminates the risk of subscapularis insufficiency. These two techniques utilize the deltopectoral interval and do not require a deltoid split for a subscapularis preserving approach: the "superior" rotator interval technique and the "inferior" subscapularis splitting technique.

Rotator Interval Operative Technique: Superior Approach

One subscapularis sparing approach is the "superior" rotator interval technique. Also known as the "above and below" technique, this approach involves resection of humeral head osteophytes through an inferior window in the subscapularis (typically 10%) and preparation as well as implantation of the humeral and glenoid prostheses through the rotator interval. This approach previously described by Zuckerman and Kwon has been reported before though much of the instrumentation has since been modified.[8]

Simovitch R, Fullick R, Zuckerman JD. Subscapularis preserving technique in anatomic total shoulder arthroplasty: the superior and inferior approach. Bull Hosp Jt Dis. 2015;73(Suppl 1):S154-60.

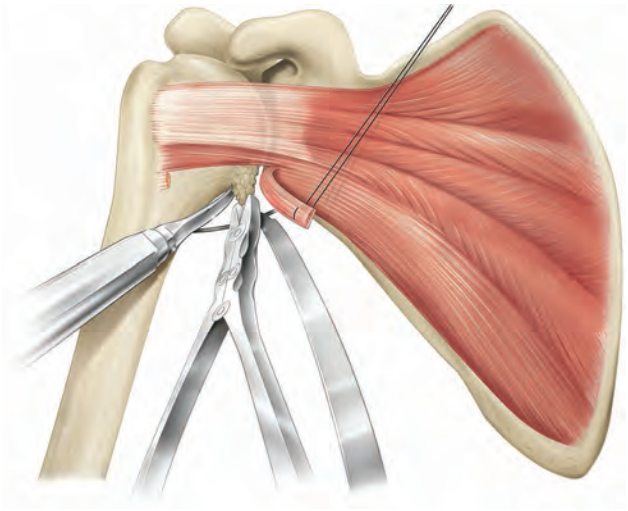

Figure 1 Inferior osteophytes are resected through a muscular window. Tendinous portion of subscapularis is not violated.

A combination of general and regional (interscalene) anesthesia is utilized. A beach chair position is utilized though the head of the bed is elevated approximately 60º to 70º, a position slightly more vertical than normal.

An incision is made approximately 1 cm lateral to the coracoid. In order to gain wider exposure, full thickness skin flaps are developed in all directions. The cephalic vein is mobilized and retracted. The subacromial and subdeltoid spaces are mobilized with the release of all adhesions through a combination of sharp and blunt dissection. Curved Mayo scissors are useful for this step. The clavipectoral fascia is incised lateral to the conjoint tendon and muscle belly, and these structures are mobilized medially. A Kolbel retractor can be inserted at this point for retraction. The coracoacromial (CA) ligament is then completely released to allow additional visualization of the rotator interval window. Hemostasis should be achieved because the acromial branch of the thoracoacromial artery travels in proximity to the CA ligament. Finally, the anterior humeral circumflex artery and two accompanying venae comitantes (three sisters) are cauterized or tied off with 2-0 silk ties. The axillary nerve should at least be palpated to note its position for protection during the remainder of the case.

The first step is exposure of the inferior humeral capsule and osteophytes. This is necessary first in order to allow greater external rotation and relaxation of the joint to facilitate the rotator interval window approach. Osteophyte resection and capsular release should proceed as in a standard aTSA. The tendon insertion of the subscapularis is preserved; however, the inferior muscular portion (approximately 5 mm to 10 mm) is released from the humeral neck and retracted inferiorly and medially using a Hohmann or substitute curved retractor, placing the axillary nerve in a safe extra-capsular position (Fig. 1). The amount of muscle released (5 mm to 10 mm) depends on the size of the osteophytes and degree of difficulty accessing the capsule posteriorly for release. With progressive external rotation, additional osteophytes and capsule can be resected utilizing electrocautery, rongeur, and small curved osteotomes.

Next, the biceps sheath is opened, and the position of the biceps is utilized to recognize the location of the rotator interval window. The biceps is then sharply removed from its insertion of the superior glenoid and is either tenotomized or tenodesed per the surgeons preference.

The anterior border of the supraspinatus and the upper rolled border of the subscapularis that define the rotator

interval are now visualized. Starting laterally, the thin rotator interval capsular tissue is excised between these two structures moving in a medial direction until the superior glenoid is encountered.

Specially designed low profile spiked Hohmann retractors with an angle are inserted anteriorly deep to the subscapularis tendon and posteriorly along the anatomic neck of the humerus deep to the posterior rotator cuff insertion (Fig. 2). Alternatively, a curved posterior rotator cuff retractor can be placed along the posterior anatomic neck and rotator cuff junction. These allow visualization of the anatomic neck of the humerus and protection of the rotator cuff insertion.

There are several methods to perform the humeral head cut with an oscillating saw. One method is to perform a free hand cut. An extra-medullary cutting guide with a version reference can be used as an aid. Through the inferior window, the surgeon's non-dominant hand can palpate the inferior border of the anatomic neck, and a retractor can be placed at this level to protect the glenoid and axillary nerve from the saw blade. The spiked Hohmann retractor anteriorly demarcates the subscapularis insertion (anterior anatomic neck), and a spiked Hohmann retractor or curved posterior cuff retractor delineates the posterior rotator cuff insertion (posterior anatomic neck), allowing an oscillating saw blade controlled by the surgeon's dominant hand to safely resect the humeral head at the anatomic neck. Alternatively, a provisional cut can be made in valgus starting at the anterior supraspinatus insertion behind the bicipital groove to open the intramedullary canal. Since this sets the depth of the humeral component at the junction of the greater tuberosity and the humeral head, an undersized female broach can be impacted and guide the oscillating saw blade appropriately to make the definitive resection. Finally, if preferred, an extramedullary cutting guide can be assembled and used to estimate the humeral head resection. The free-hand cut best allows a reproduction of the patient's unique anatomy since version and inclination can be cut precisely based on the patient's anatomic neck instead of being limited by a guide or female broach. If resected as one piece, the resected humeral head is measured to obtain an estimate of the prosthetic head diameter and thickness.

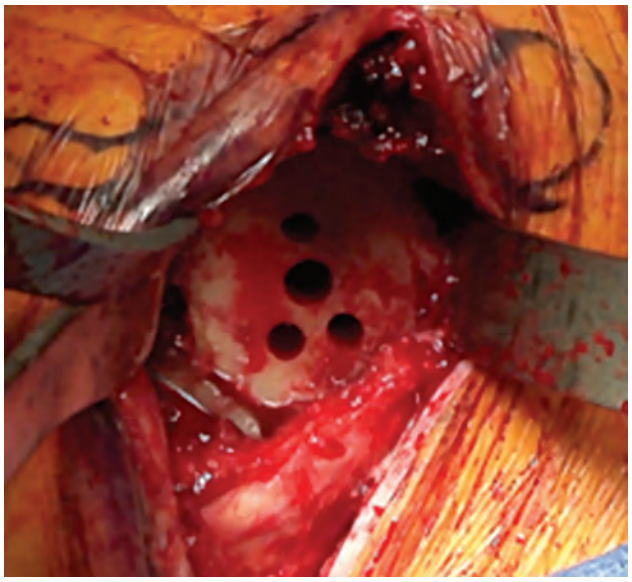

Figure 3 Exposure is easily obtained through the rotator interval as long as an adequate head resection is done and retractors are appropriately placed.

The position of the arm for humeral preparation is different than in standard aTSA. By adducting and extending the humerus, optimum exposure of the cut humeral surface is obtained through the rotator interval. The low profile Hohmann retractors are then used to retract the anterior and posterior rotator cuff, thus widening the exposure through the rotator interval. Reaming and broaching are done in a standard fashion, however a modified low-profile broach handle is utilized to facilitate access through the rotator interval. The last size broach is left in the humeral canal with a protective metal disc attached to protect the humeral cut surface during glenoid preparation.

The arm is returned to a neutral position and variably externally rotated to allow glenoid exposure. Minimal external rotation is necessary. The glenoid is exposed by placing a two pronged glenoid retractor anteriorly along the scapular neck and a specialized posterior glenoid retractor posteriorly on the edge of the glenoid. A forked "Playboy" retractor is typically useful along the inferior glenoid to lever the humerus inferiorly and posteriorly allowing wide exposure of the glenoid face. Soft tissue and capsular release is performed. The glenoid is prepared in standard fashion though an articulating drill and reamer are utilized in cases where exposure is more limited (Fig. 3). Subsequent to preparation, a final standard all polyethylene pegged or keeled component or a caged hybrid glenoid component can be inserted. The glenoid should be inserted before the humeral component is implanted.

The arm is again adducted and extended, while the spiked Hohmann retractors are used to retract the margins of the rotator interval. Offset of the humerus is judged by comparing the center of the trial prosthesis to the margins of the humeral cut surface. If there is greater offset, a 4.5 mm modified short replicator plate is used, and if there is minimal offset, a 1.5 mm modified short replicator plate is used. A low profile humeral plate dial is coupled to the short replicator plate. The replicator plate sits in the well of the broach or trial humeral component. Low profile instruments are used to rotate the replicator plate and humeral plate dial into the appropriate version, inclination, and offset to yield the best metaphyseal coverage and anatomic restoration. Once the position is satisfactory, a low profile wrench is used to tighten the torque screw. The broach/trial are removed, and the offset of the humeral head relative to the offset of the replicator plate is recorded because this

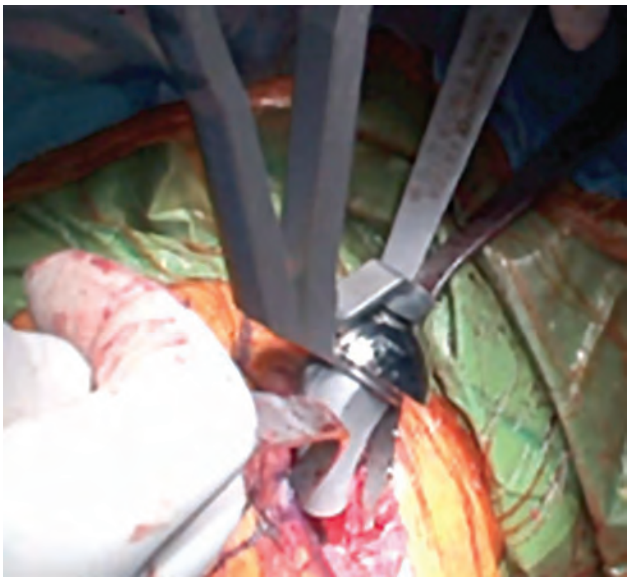

Figure 4 A specialized low profile prosthesis inserter helps to impact the assembled stem and humeral head into the humeral canal through the rotator interval and around the prominent coracoid.

dual eccentricity will be matched during assembly of the final prosthesis.

A back table assembly of the final prosthesis is performed. It is assembled to match the trial position and sizes. The replicator plate position is matched (offset, version, and inclination) and secured to the final stem with a torque limiting wrench and torque screw. The humeral head position is dialed to the appropriate offset based on the trial position and impacted in usual fashion to engage the Morse taper.

The arm is positioned in adduction and slight external rotation providing improved exposure through the rotator interval. The margins of the rotator interval can be retracted with small Senn retractors. A unique low profile insertion device is used to grasp the assembled prosthesis. The humeral prosthesis is inserted into the intramedullary canal at first externally rotated to avoid the coracoid and then gradually internally rotated after the coracoid is cleared (Fig. 4). The insertion handle is impacted until the prosthesis assumes an appropriate position. The position is verified through the inferior window.

After irrigation and hemostasis is achieved, the rotator interval is closed starting from lateral to medial with interrupted non-absorbable sutures. The inferior subscapularis window can be repaired based on surgeon preference. A drain is used if necessary and depending on surgeon preference.

A sling is provided for comfort only. Active and active-assisted ranges of motion are instituted immediately after surgery, and strengthening is begun once forward elevation to 90° is achieved. Patients can immediately use the arm for activities of daily living (ADL).

Subscapularis Split Operative Technique: Inferior Approach

An alternative subscapularis sparing approach allows all steps of an aTSA to be performed below the subscapularis without opening the rotator interval. This technique has been previously described for use in humeral head resurfacing by Savoie.[9] The patient is placed in a beach chair position. A deltopectoral approach is utilized. Once the subscapularis is identified and the three sister vessels are tied off or coagulated, the lower one-half to lower one-third of the subscapularis is released from the lesser tuberosity (Fig. 5). The humerus is externally rotated allowing the capsule to be released from the inferior humeral neck as far posteriorly as possible. The middle glenohumeral and

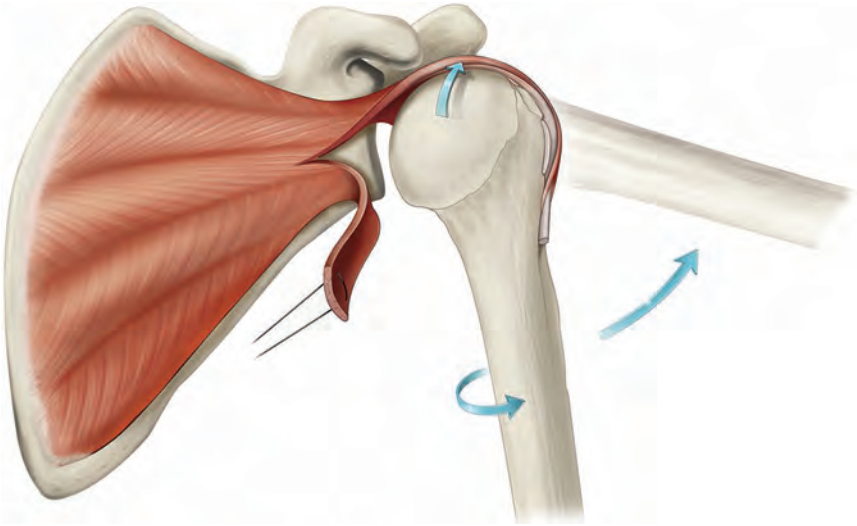

Figure 6 Subscapularis is flipped over the humeral head clearly demonstrating the anatomic neck of the humerus while the head is dislocated inferiorly.

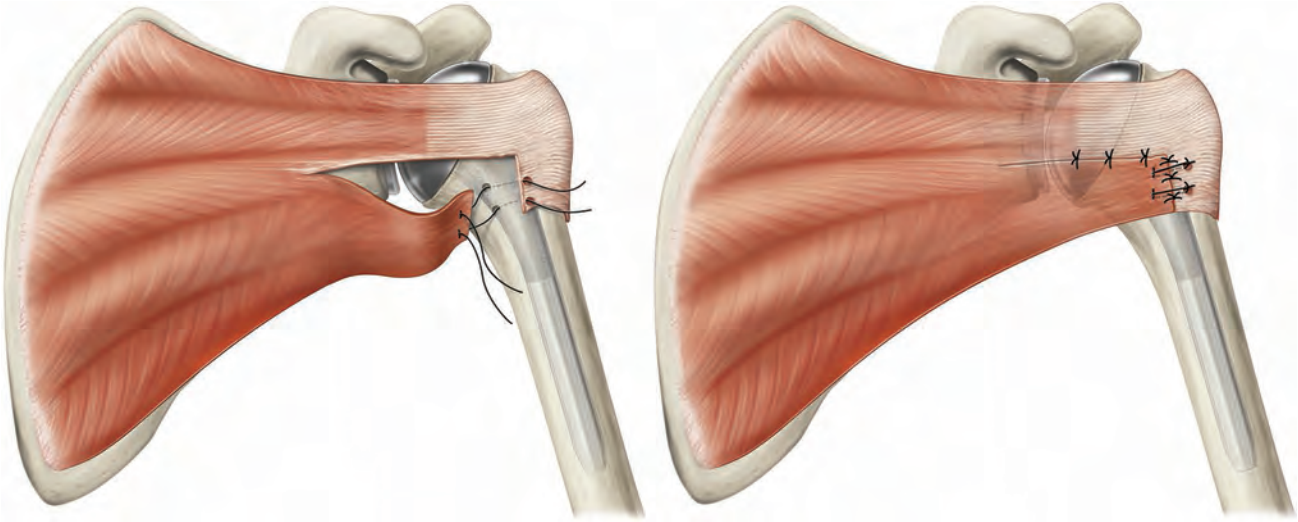

Figure 7 Repair of subscapularis split. A combination of modified Mason-Allen stitches and figure of eight stitches with #2 non-absorbable braided sutures are done.

coracohumeral ligaments are released. A curved rotator cuff retractor is then inserted along the anatomic neck posteriorly as the arm is abducted and externally rotated and the humeral head is flipped under the upper subscapularis (Fig. 6). A Chandler retractor placed medially is used to lever the humerus anteriorly. All osteophytes are removed. With this exposure, the humeral head is resected with an oscillating saw similar to a routine subscapularis tenotomy exposure. The humerus is reamed and broached utilizing the standard instrumentation. A trial component is inserted into the intramedullary canal, and the humerus is retracted posteriorly with a bent posterior glenoid retractor while a two pronged anterior retractor is utilized to retract the inferior subscapularis and pectoralis major medially. The arm is placed in abduction and externally rotated. A special bent low profile spiked Hohmann is placed superiorly and used to retract the upper subscapularis superiorly.

The glenoid is prepared in standard fashion, and a hybrid caged pegged glenoid component is impacted into the glenoid after cementing the peripheral peg holes. Next, a Chandler retractor is again used to lever the humerus anteriorly. Prior to insertion of the final humeral implant, two drill holes are made on either side of the lesser tuberosity inferiorly, and two #2 braided sutures are passed through these holes for inferior subscapularis repair. The humeral stem is impacted, and the offset, version, and inclination of the head are determined by trialing with a definitive 4.5 mm or 1.5 mm offset replicator plate depending on the amount of offset. Once the replicator plate position is set, the humeral head of appropriate size and height is rotated to the correct offset and impacted. The humerus is reduced, and the inferior subscapularis is repaired with the sutures previously passed through bone tunnels with a modified Mason-

Allen stitch. The horizontal split between the inferior and superior subscapularis is repaired side to side with a #2 braided suture (Fig. 7). A drain is placed based on surgeon preference. Immobilization and therapy progression is similar to the rotator interval approach detailed above.

Discussion

Subscapularis tear and dysfunction occur with a significant frequency following aTSA performed with a subscapularis takedown.[2-6] Though worse clinical outcomes have been associated with subscapularis insufficiency, failure of subscapularis healing is often clinically silent; therefore, it may be under appreciated. Subscapularis insufficiency is a mode of aTSA failure, and Miller and colleagues reported a 5.8% revision rate after aTSA in a large series.[5] Avoiding subscapularis insufficiency is desirable. A subscapularis preserving approach avoids this pitfall and allows aggressive physical therapy and early return to ADLs.

Lafosse and coworkers previously described a rotator interval approach to aTSA.[7] This technique involved a deltoid split and experienced inadequate osteophyte resection (47%) and humeral head undersizing (29%). This technique did not utilize an inferior window. We believe the rotator interval (with inferior window) and subscapularis splitting techniques detailed above pose a significant advantage over this previously described technique by avoiding a deltoid split and lessening the occurrence of humeral head undersizing and inadequate osteophyte resection. The addition of an inferior subscapularis muscular window in the rotator interval approach allows the surgeon to visualize and resect all osteophytes directly while also ensuring adequate humeral head sizing and positioning. In addition, the subscapularis splitting technique allows complete inferior humeral neck visualization for osteophyte resection and sizing. We have not appreciated any clinical sequelae of violating the inferior muscular portion of the subscapularis (10%) with or without its repair at the conclusion of the surgery. Ding and associates reported on the results of the rotator interval approach with an inferior window for osteophyte resection compared to subscapularis tenotomy for aTSA.[10] Despite the inferior window, they found significantly more postoperative osteophytes ($p = 0.001$) in the subscapularis preserving group (29%) compared to the subscapularis tenotomy group (3%). In addition, although they did not find a significant difference in mean head size discrepancy (difference between prosthetic head diameter and native humeral head diameter) between groups, they did find that the subscapularis preserving group had a greater number of outliers defined as a mismatch larger than 4 mm. Thus, humeral head sizing and osteophyte retention continue to be a concern with the rotator interval technique. The alternative subscapularis split technique allows direct visualization of the humeral anatomic neck facilitating osteophyte resection and humeral head sizing and positioning although sizing of the head superiorly can become more difficult because of poorer visualization around the rotator interval tissue.

There are appreciable differences between the rotator interval and subscapularis split techniques. The main challenges with the rotator interval approach are the difficulty in sizing the humeral head and precisely replicating offset of the humeral head because the window is narrow and requires a back-table assembly of the final prosthesis. However, with experience, this becomes easier and more precise. In addition, the rotator interval technique requires extended retraction on the subscapularis muscle and tendon with indeterminate effects on the muscle and tendon function, though no ill effects have been clinically appreciated. While the subscapularis split allows an en face exposure of the humerus most similar to traditional open surgery and facilitates in situ assembly and precise head positioning, this approach involves tenotomy of the lower one-half to lower one-third of the subscapularis with repair, which may have biomechanical consequences on the strength of the subscapularis. However, Savoie has reported on 50 patients who underwent humeral head resurfacing with a subscapularis splitting approach, releasing the inferior 30% to 50% of the subscapularis. All patients had subscapularis strength equal to the nonoperative side, and there were no radiographic subscapularis failures or cases of subscapularis muscle atrophy.[9]

We have identified the subscapularis preserving approaches to aTSA detailed above to be safe and reproducible. There is a relatively steep learning curve. This technique should not be used in a revision setting where wide exposure is necessary. Relative contraindications to these techniques include obesity, significant medial glenoid erosion, and situations where glenoid bone grafting is needed. Care should also be taken in patients with severe rotator cuff tendinopathy due to the risk of rotator cuff peel back or iatrogenic injury by overzealous retraction.

Future larger studies will examine and report on the clinical and radiographic outcomes of aTSA through subscapularis preserving (rotator interval with inferior window and subscapularis split) approaches compared to the standard subscapularis tenotomy, peel, and osteotomy. Furthermore, the rotator interval and subscapularis split approaches will be compared to each other prospectively for clinical outcome, survivorship, and accuracy of anatomic reconstruction. In addition, future studies will evaluate if the percentage of subscapularis release with the subscapularis split technique impacts the strength of the intact portion of the subscapularis and influences the rate of subscapularis healing or failure. Finally, postoperative radiographic studies will be performed to confirm the integrity of the anterior superior rotator cuff tendon insertion and muscle architecture following both subscapularis preserving approaches in a large series.
